This is a digital copy of a book that was preserved for generations on library shelves before it was carefully scanned by Google as part of a project to make the world's books discoverable online.

It has survived long enough for the copyright to expire and the book to enter the public domain. A public domain book is one that was never subject to copyright or whose legal copyright term has expired. Whether a book is in the public domain may vary country to country. Public domain books are our gateways to the past, representing a wealth of history, culture and knowledge that's often difficult to discover.

Marks, notations and other marginalia present in the original volume will appear in this file - a reminder of this book's long journey from the publisher to a library and finally to you.

Usage guidelines

Google is proud to partner with libraries to digitize public domain materials and make them widely accessible. Public domain books belong to the public and we are merely their custodians. Nevertheless, this work is expensive, so in order to keep providing this resource, we have taken steps to prevent abuse by commercial parties, including placing technical restrictions on automated querying.

We also ask that you:

+ *Make non-commercial use of the files* We designed Google Book Search for use by individuals, and we request that you use these files for personal, non-commercial purposes.

+ *Refrain from automated querying* Do not send automated queries of any sort to Google's system: If you are conducting research on machine translation, optical character recognition or other areas where access to a large amount of text is helpful, please contact us. We encourage the use of public domain materials for these purposes and may be able to help.

+ *Maintain attribution* The Google "watermark" you see on each file is essential for informing people about this project and helping them find additional materials through Google Book Search. Please do not remove it.

+ *Keep it legal* Whatever your use, remember that you are responsible for ensuring that what you are doing is legal. Do not assume that just because we believe a book is in the public domain for users in the United States, that the work is also in the public domain for users in other countries. Whether a book is still in copyright varies from country to country, and we can't offer guidance on whether any specific use of any specific book is allowed. Please do not assume that a book's appearance in Google Book Search means it can be used in any manner anywhere in the world. Copyright infringement liability can be quite severe.

About Google Book Search

Google's mission is to organize the world's information and to make it universally accessible and useful. Google Book Search helps readers discover the world's books while helping authors and publishers reach new audiences. You can search through the full text of this book on the web at `http://books.google.com/`

Geological Survey Branch,
Department of Mines and Agriculture,
Sydney, 12th December, 1906.

Sir,

I have the honour to submit for publication Part II of Memoir No. 13 (Palæontological Series) on the *Silurian and Devonian Corals of New South Wales*, by Mr. Robert Etheridge, Junior, Curator of the Australian Museum.

This volume, on the genus Tryplasma, forms the second contribution by Mr. Etheridge towards the description and classification of the fossil corals which characterise the Upper Silurian and the so-called Siluro-Devonian passage beds, particularly along the Murrumbidgee River, in the neighbourhood of Yass.

Mr. Etheridge's work is of special interest in view of the importance of establishing a dividing line between the Silurian and Devonian rocks of New South Wales.

I have the honour to be,
Sir,
Your obedient servant,
EDWARD F. PITTMAN,
Government Geologist.

The Honourable S. W. Moore, M.P.,
Minister for Mines and Agriculture.

Author's Preface.

The material employed in the present number of the "Monograph of the Silurian and Devonian Corals of New South Wales," forming Part II of that work, and comprising the genus *Tryplasma*, is derived chiefly from the collections of the Australian Museum, and the Mining and Geological Museum, attached to the Department of Mines, Sydney. Specimens in the cabinets of the Geological Department, University of Sydney, and the Geological Class-room at the Technical College, Ultimo, have also been made use of.

The specimens in the Mining and Geological Museum and the Australian Museum we owe mainly to the untiring efforts of Mr. Charles Cullen, late Collector to the Geological Survey, and Mr. A. J. Shearsby, late of the Australian Joint Stock Banking Company, at Yass, respectively, and were placed at my disposal by Mr. E. F. Pittman, A.R.S.M., Under Secretary for Mines and Agriculture, on the one hand, and the Trustees of the Australian Museum on the other. The University corals were chiefly collected by the late Mr. Charles Jenkins, L.S., of Yass, and my thanks are tendered to Prof. T. W. E. David, B.A., for the use of them, and to Mr. C. A. Süssmilch, Lecturer on Geology, Technical College, for the loan of those in his teaching collection, collected by himself.

As in all my work of late years, I have been cordially assisted by Mr. W. S. Dun, Palæontologist to the Geological Survey.

R. ETHERIDGE, Junr.

Sydney, May, 1906.

I.—INTRODUCTION.

THREE species, referable to the genus *Tryplasma*, Lonsdale, as I understand it, have, so far, been described from Australian material, all from Upper Silurian strata. The first, *T. Lonsdalei*, mihi, may be regarded as the Australian type, and represents the fasciculate forms; the second, *T. wellingtonensis*, mihi, represents the turbinate-conical species, and the third, *T.* (?) *Murrayi*, mihi, again appertains, more or less, to the fasciculate division. The first two occur in New South Wales and the third in Victoria.

At the inception of my study of this remarkable genus, I had no conception of the wealth of material available, nor of the protean character of the species comprising it. *Tryplasma* is one of the most important genera met with in our Silurian rocks, several of its species indicating well defined stratigraphical horizons, just as the late Dr. G. Lindström has noted in the case of the occurrence of his *T.* (*Pholidophyllum*) *tubulatum* in the Gotland Limestone. The occurrence of *Tryplasma* in Australia, so far as its stratigraphical distribution is at present known, always indicates rocks of Upper Silurian age. At any rate only one doubtful instance to the contrary is known, although in Germany, where it has been recognised under the names of *Calophyllum* and *Cœlophyllum*, it passes into the Stringocephalus Limestone of the Middle Devonian. The importance of *Tryplasma* as a stratigraphical factor will be readily understood when its occurrence at no less than forty-six different localities is pointed out. It is also a world-wide form, the geographical distribution having been indicated by Lindström under the name of *Pholidophyllum*.

II.—HISTORY OF THE GENUS TRYPLASMA.

THE history of *Tryplasma* is a peculiar one and must be studied in detail to ensure a proper understanding of the following remarks:—

1845.—We owe the name to Mr. W. Lonsdale,[1] who employed it for a coral from the Silurian rocks of the Ural Mountains, and regarded it as a sub-genus of *Cyathophyllum*. The only species described was *T. æquabilis*,[2] but in a foot-note to his description the author included also *Cyathophyllum articulatum*, Wahl., or a coral he took to be this form. In the explanation of his plate he wrote as follows:—"The coral, believed to be the *Cyathophyllum articulatum* of M. Hisinger, is given to prove that the peculiar characters exhibited by *Tryplasma æquabilis* occur in another coral with a sufficient amount of a differential structure to warrant the establishing of a second species, and, therefore, the proposing of the sub-genus.[3]

The type, *T. æquabilis*, is a cylindrical, solitary coral, with a thin outer wall, a broad central, tabulate area, an outer narrow septal zone, the septal lamellæ numerous, alternately larger and smaller, and round "foramina"; the tabulæ were conceived to be continuous through the septal lamellæ to the outer wall. This is practically Lonsdale's definition, although not exactly in his words. The figure[4] of the supposed *C. articulatum* displays a similar structure to that of *T. æquabilis*, and in addition, being a compound form, the corallites united by connecting bars [fistulæ], rendering the corallum more or less fasciculate.

A thorough conception of the meaning of Lonsdale's "foramina" is essential to a true understanding of the structure of *Tryplasma*. He said: "The peculiarities consist,—first, in the lamellæ [septal lamellæ][5] of the outer area being pierced, from the inner surface of the wall, through their whole breadth by well defined relatively larger foramina, terminating on the inner edge [free inner border of the septal lamellæ] in a distinct row of short tubuli; and, secondly, in the total absence of interstitial vesicular laminæ

[4] Lonsdale—*Loc. cit.*, t. A, f. 8, 8*a*.
[5] The words within square brackets are mine.

[dissepimental tissue] at every period of growth." Lonsdale further added that the "diaphragms" [tabulæ] were simply continued between, and possibly through, the "lamellæ" [septal lamellæ] to the outer wall, the extension of the lamellæ inwards being limited. That is to say, Lonsdale conceived a Rugose coral, in which the septa were pierced by pores running transversely through their substance, the pores in question terminating on the inner face edges of these lamellæ in short tubuli. Had Lonsdale grasped the fact that he was examining a mould, or natural intaglio, instead of a natural cameo, he would not have fallen into the error he did, through a misreading of the structural details before him, which, when viewed in this light, are of actual generic value.

Some years ago, when describing the first Australian species of *Tryplasma*, I offered an explanation of the apparent discrepancy in Lonsdale's specimens.[1] The "pores" are not only visible on entirely or partially decorticated specimens, *i.e.*, on those in which the proper wall and septal zone are wholly or in part removed, but also on internal casts, pure and simple. Now, bearing in mind that the septal apparatus consists, first, of narrow, vertical lamellæ, and secondly, of free spines protruding inwards from the free edges of the latter, it naturally follows that on disintegration or partial disintegration of these tissues taking place, grooves running vertically are left, bearing at regular intervals pores or small round openings, the grooves representing the septal lamellæ [lamellæ of Lonsdale], the pores his "foramina," and their extension inwards his "tubuli"; an examination of many of the figures on the accompanying plates will exemplify this far better than a lengthy explanation. In other words, Lonsdale did not endeavour to reconstruct in his mind's eye his imperfect specimen of *T. æquabilis*. Had he done so, he would not have afforded Lindström an excuse for shelving his generic name.

1852.—In their great work "Monographie des Polypiers Fossiles des Terrains Palæozoïques," Messrs. H. Milne-Edwards and Jules Haime wrote of *Tryplasma*[2]:—"If this peculiarity [the piercing of the septal lamellæ by pores, &c.] really exists, it will assuredly be quite sufficient to distinguish this genus of Cyathophyllidæ from all the other forms of the same group; but we are led to believe that Mr. Lonsdale, when he established the division, was deceived by an appearance, and we have not seen anything similar in one

[1] Etheridge—Rec. Geol. Survey N. S. Wales, 1890, II, Pt. 1, p. 17.

[2] H. Milne-Edwards and J. Haime—Archiv. Mus. Hist. Nat., 1852, V, p. 393.

of the species which he mentioned and named *Tryplasma articulata.*" The authors further refer *T. articulata*, Lonsdale, to their *Cyathophyllum* (?) *Loveni*[1], describing the septal lamellæ as larger and smaller alternately, close, thick, and with very close, strong teeth [septal spines], the primary septa corresponding to the intercostal grooves, and the secondary to the costæ.

1854.—Messrs. H. Milne-Edwards and J. Haime used similar language in describing *C. Loveni* in their second work.[2]

1856–1857.—In 1856 the Chevalier E. d'Eichwald, in his "Geographical Distribution of Russian Fossil Remains,"[3] and, in 1857, Dr. von Grünewaldt in a list of the Silurian fossils of the Ural,[4] record *Tryplasma æquabilis*, Lonsdale, but without further remarks other than the localities.

1856.—The Brothers Sandberger described two species of *Amplexus* from the Stringocephalus Limestone of Nassau—*A. tortuosus*, Phillips,[5] and *A. stigmatophorus*, Sandb.[6] As to the first of these, no definite opinion can be passed, but no doubt need exist as to the nature of the second; the longitudinal view of the corallum, that of a weathered specimen, most unquestionably displays the perforations left by the dissolved-away septal spines.

1858–1861.—Mr. E. de Fromental followed Edwards and Haime in uniting *Tryplasma articulata*, Lonsdale, with *Cyathophyllum Loveni*, Ed. and H.[7]

1861.—The Chevalier E. d'Eichwald, rather more cautious than Edwards and Haime, refers[8] to *Tryplasma* [*Trypelasma* he spelt it], as "perhaps" referrable to *Cyathophyllum*. He further described a coral from the Silurian rocks of the island of Oesel as *Omphyma fastigiatum*[9] which Lindström subsequently included in his *Pholidophyllum tubulatum*. The septal spines, anchoring rootlets [radiciform processes], and calicinal budding figured by d'Eichwald at once denote its relation to *Tryplasma*.

1865–6.—In his very remarkable paper on the "Corals of the Palæozoic Formations," Mr. Rudolph Ludwig described and figured a small coral as *Acanthoconium inversum*,[1] which presents all the typical septal features of a turbinate form of *Tryplasma*. His very interesting figures re-illustrate, in a great measure, the very condition of preservation originally described by Lonsdale, *i.e.*, an internal cast in which the longitudinal lines of the primary and secondary septal spines are represented by tube-holes penetrating the matrix; the accuracy of his diagrammatic figure of the septal system is, however, open to question. At a later stage, in the same paper, the Author describes the cylindrical form, afterwards termed *Pholidophyllum tubulatum* by Lindström, as *Tæniocyathus* or *Tæniolopas spinosa*,[2] which is an excellent representation of a cylindrical *Tryplasma*—form, budding, septal-lamellæ with spines, and tabulæ. At least two species of Mr. Rudolph Ludwig's genus *Ptychocyathus*,[3] viz., *P. profundus* and *P. granulifer*, are referable to *Tryplasma*. The pore-like holes left by the dissolved-away septal spines are visible in the figures of both, and in the enlargement (Fig. 1*e*) of a portion of the weathered surface of *P. profundus* both the primary and secondary rows of septal spines are excellently represented.

1870.—In this year Dr. G. Lindström[4] proposed his genus *Pholidophyllum*, selecting as the type *Cyathophyllum Loveni*, M. Edw. and Haime, remarking—"Its strange exothecal covering in scaly rows, its septa, its well-developed tabulæ, its double costæ, and the complete want of dissepimental structure between the septa, justify my forming a new genus out of it, which I propose to name *Pholidophyllum*."

1873.—The genus *Acanthodes* was next proposed by Dr. W. N. Dybowski[5] for the reception of several Silurian species, either simple or sub-fasciculate, provided with anchoring rootlets on the underside of the corallites, and narrow lamellar septa of two orders produced into spines along their free edges. The tabulæ are variously formed, occupying the whole of the visceral space, but not reaching the wall, says Dybowski—a manifest error, although it will be remembered Lonsdale made the same remark; no allusion is made to the presence of either a fossula, dissepiments, or exothecal scales. Reproduction was observed only in one species (*A. tubulus*), the young corallites occasionally

[5] Dybowski—Mon. Zoantharia Scler. Rugosa, Pt. 1, 1873, p. 108.

budding from the sides of the parent stem[1]—lateral or parietal gemmation in other words. From what has already been said of the true structure of *Tryplasma*, it will be at once apparent that, with the exception of the parietal gemmation, that of *Acanthodes* is identical with the former, as was first pointed out by Dr. Lindström.

Dybowski also resuscitated Dana's genus *Calophyllum*[2] for other corals from the same area, consisting of simple and conical, or aggregated corallites, with septal lamellæ of two orders, the secondary granular. Tabulæ of various forms occupy the whole breadth of the visceral cavity. Dybowski regarded these corals as intermediate between *Cyathophylloides* and *Amplexus*. It is possible that the first species described may be a *Tryplasma*, although he mentions the presence of lateral buds, and one is shown in the species referred to (*C. Roemeri*).[3]

1873.—Two species were referred by Professor F. H. E. Kayser to *Amplexus* that have every appearance of *Tryplasma*, viz. *A. tortuosa*, Phill.,[4] and *A. irregularis*, Kayser,[5] are from the German Devonian. In the former, delicate septa [? septal spines] are shown in a transverse view of the corallum, with distant horizontal tabulæ, and a fistula in the longitudinal view. In the latter, similar septa, and vesicular tabulæ, the vesicles closely resembling those of several of our N. S. Wales corals. Nothing of a decisive nature can be gleaned from Phillips' description and figure of *A. tortuosa*.[6]

1876.—Amongst his synonyms of *Pholidophyllum tubulatum*, Lindström included *Cyathophyllum radicula*, Rominger, a coral from the Niagara Group of North America. Rominger says[7] the cylindrical corallites are strongly attached by their bases to other bodies, and strengthened by anchoring [radiciform] processes. There are "about" sixty alternately larger and smaller crenulated septal lamellæ, which either extend to the centre of the bottom of the calice formed by the uppermost tabula, or the latter is smooth, or again faintly carinate or granulate. The reference of *Cyathophyllum radicula* to *Tryplasma* is hardly warranted by the description, more particularly as the presence of a septal fossula is foreshadowed, or in Rominger's words "a septal fovea is rarely indicated."

[7] Rominger—Geol. Survey Michigan—Lower Peninsula, 1873-76, III, Pt. 2, 1876, p. 109, t. 39, f. 3.

1881.—Dr. Georg Meyer, in a paper on the "Rugose Corals of the East and West Prussian Diluvial Formation," adopted Dybowski's name of *Acanthodes*, placing *Tryplasma* as a synonym under it; one species was described, *A. borussicus*, Meyer.[1] Notwithstanding Dr. Meyer's involved description, this is clearly a species of *Tryplasma*. The illustrations display the typical spined septal lamellæ, wide central tabulate area, and the absence of dissepiments.

1881.—Dr. Clemens Schlüter, like Dybowski, employed Dana's dubious name *Calophyllum*. He described a coral from the Stringocephalus Limestone as *C. paucitabulatum*.[2] The corallum is more or less fasciculate, consisting of elongately conical, or almost cylindrical corallites, sometimes united to one another by fistulæ. The septa are quite rudimentary, but still of two orders, the tabulæ horizontal and very widely separated apart; there are neither dissepiments, nor fossula. Reproduction is effected by profuse calicinal budding, from three to six buds, having one-half of their walls at first in common with the parent calice. As to the presence of a fossula, Dr. F. Frech[3] believed he could detect such a depression in a specimen of *C. paucitabulatum* examined by him; but Schlüter subsequently controverted this.[4] The latter considered his species to differ from *Amplexus* in the absence of this fossula, distance apart of the tabulæ, and the mode of reproduction. This coral bears a most remarkable resemblance to some of our *Tryplasmæ*, a resemblance borne out by the fact that later writers described the narrow septal lamellæ as spined; this will be again referred to later.

1882.—In his more extended and valuable paper on the "Palæozoic Operculate Corals," Dr. G. Lindström wrote as follows[5]:—"It is fitting to mention also two others, partly known for a long time, which have been found to possess round the outer walls, and at the edge of the calice, exothecal structures, to a certain extent homologous with and in all respects comparable to the opercula of the former [*Calceola*, *Goniophyllum*, *Rhizophyllum*, &c.]. The most common is that which forms the genus *Pholidophyllum*."

Under *Pholidophyllum*, Lindström placed *Tryplasma*, Lonsdale, and *Acanthodes*, Dybowski, and said the genus "should perhaps have been called *Tryplasma*; but this name having been founded on an error, according to

[5] Lindström—Bihang K. Sv. Vet. Akad. Handlingar, 1882, VII, No. 4, p. 63.

which the septal spines and septal lamellæ should be perforated by canals, a supposition caused by the broken lower parts of the spines, I have proposed the new name . . . . based upon the peculiarities of the outer scales" [exothecal structures of the preceding paragraph]. Lindström was unquestionably correct in placing Dybowski's *Acanthodes* as a synonym, both on account of its structure and, as he said, by preoccupation as the name of a fish (*Acanthodes*, L. Agassiz).

On the more important point, however, of the substitution of the name *Pholidophyllum* for that of *Tryplasma*, I formerly wrote as follows[1]:—"I regret that I cannot agree with Dr. Lindström in the abolition of *Tryplasma*. If every generic name in Palæontology is to be abolished because an original misconception as regards its structure was made, few of the older genera would stand. Granting that a genus has been figured and described to the best of an author's knowledge and the material before him, it seems difficult to understand how his work can be set aside. I therefore adopt *Tryplasma* as typified by Lonsdale, and described by Lindström under the name of *Pholidophyllum*, with this exception—I believe that *Palæocyclus* should be eliminated from the latter."

The coral here selected by Lindström as the type of his genus was the *Tubiporites tubulatus*, Schlotheim, and a very full synonomy was given, inclusive of both species comprised by Lonsdale in his *Tryplasma*, and also *Cyathophyllum* (?) *Loveni*, previously referred to under Milne-Edwards and Haime and Lindström (1870). This synonymy affords a very complete bibliography of the coral up to the date of publication of Lindström's paper from his point of view, and will serve to amplify the historical references here given. The corallum in *Pholidophyllum tubulatum* is described as compound, budding in quadruple divisions, but in this "compound" (or, as I would prefer to call it, "sub-compound") growth Lindström recognised two conditions in the one species, the "forma primaria" and the "mutatio." The former is broad conical, the latter cylindrical, either fixed by anchoring rootlets extending from near the distal end of the corallum, or by the whole base; the rootlets are either simply tubular or tabulate. The septal lamellæ are of variable width, and of two orders, forty of each, denticulated on their free edges, and granulated on the lateral faces; there is no fossula. A wide central tabulate area is left, the tabulæ vertically spined on their upper surfaces. Gemmation is calicular, four new corallites arising within the calice

[1] Etheridge—Rec. Geol. Survey N. S. Wales, 1890, II, Pt. 1, p. 15.

of the parent, not simultaneously, but in succession, each from its own side and meeting in the middle. The most peculiar feature of *P. tubulatum* is the occurrence of exothecal structures in the form of "numerous curious little scales" on the pseudocostæ or rugæ of the simple forms, arranged longitudinally, and "which generally fall off," each pair of rugæ bearing two rows of scales. These are described in detail by Dr. Lindström, and are compared to the opercular valves of *Arœopoma prismatica*; the scales in question are not found on the compound corallums of *P. tubulatum*. The whole structure of the latter, omitting these exothecal scales from consideration, is precisely that of *Tryplasma*.

1882.—The structure of the coral already referred to as *Cyathophyllum* (?) *Loveni*, or, as it is sometimes spoken of by Authors, *Pholidophyllum Loveni*, has been very fully treated of by Mr. G. von Koch.[1] He confirmed the remarks of Edwards and Haime on the presence of spiniferous septal lamellæ. The tabulæ, and other points of structure, including the gemmation, are strictly those of *Tryplasma* as revealed in Australian specimens. Koch's figures of the budding are very valuable, as they illustrate the gradual appearance of the young corallites from the earliest stage in one and the self-same parent corallite. In this series of five figures we trace the appearance of four buds, each one commencing as a small inwardly convex continuation of the mother wall, gradually enlarging and extending inwards until the whole of the parent calice is filled up.[2] Even more interesting, however, is the extension inwards of the maternal septal spines within the boundary of a bud to become the peripheral septal laminæ and spines of the latter, whilst those springing from the inner wall of the bud are a new creation; these buds are bilaterally symmetrical. A glance at the gemmation of our *T. princeps*, *T. liliiformis*, &c., will at once indicate how close a connection there is between their mode of increase and that of *P. Loveni*.

1883.—In this year Dr. Lindström, in a most useful paper—"Index to the Generic Names applied to the Corals of the Palæozoic Formations,"—again placed *Tryplasma* as a synonym of *Pholidophyllum*.[3]

1883.—In the volume of Richthofen's great work on China, devoted to Palæontology, the same eminent describer of Palæozoic Corals described and figured three species of *Amplexus* of Upper Silurian age, viz., *A. viduus*,

[1] Koch—Palæontographica, XXVIII, 6 Lief, 1882, pp. 216-219.
[2] Koch—*Ibid.* t. 43 (1), f. 18-22.
[3] Lindström—Bihang K. Sv. Vet.-Akad. Handl., 1883, VIII, No. 9, p. 12.

A. distans, and *A. appendiculatus*.[1] Of these, the figures of the second and third exhibit undoubted evidence of *Tryplasma* characters in the presence of spiniform septal lamellæ, thickened walls, and characteristic features of the tabulæ.[2] In the longitudinal section of *A. distans* the septal spines are visible in the intertabular spaces or old visceral chambers; in the horizontal section the thick tooth-like terminations of the septal spines send off delicate linear filaments when a cycle impinges on a tabula in precisely the same manner that the similar organs do in some of our indigenous species. In the horizontal section of *A. appendiculatus* a like feature is observable, whilst in the longitudinal section of the same coral[3] both the septal spines and vesicular tabulæ are visible, the vesicles long and lenticular; radiciform processes are also present.

1883.—The late Prof. Ferdinand von Roemer proposed the name *Cœlophyllum*[4] to take the place of *Calophyllum*, Dana, already referred to, on the ground that it is altogether doubtful what Dana intended to include in his genus. As his type, Roemer selected Schlüter's *Calophyllum paucitabulatum*, and added to its definition the important statement that the radiating lamellæ in his specimens were finely denticulated and delicately notched, thus supporting the otherwise general *Tryplasma*-like appearance of this coral.

1885.—Mr. F. Maurer, in his "Fauna of the Waldgirmer Limestone near Griessen," referred two corals to *Acanthodes*, Dybowski, *A. retinens*,[5] and *A. pastinatus*,[6] but the illustrations do not satisfactorily remind me of Acanthodian characters. Under *Calophyllum* is placed another coral (*C. serratum*[7]) which may be a *Tryplasma*, presenting the sectional transverse appearance of the genus in which the septal lamellæ are united by a thick peripheral zone of stereoplasma, with the characteristic toothed inner free edge.

1891.—In his "Chart of the Rugose Corals," Mr. W. H. Sherzer[8] included in *Pholidophyllum*, Lindström, both *Tryplasma* and *Acanthocyclus*, Dybowski. He also combined with these "*Scarithodes*," Dyb., a name I am quite unacquainted with, unless it is a misprint for *Acanthodes*.

1894.—In a paper on "East-Prussian and Eastern West Prussian Silurian Corals," Mr. W. Weissermel described *Amplexus borussicus.*[1] The corallum is evidently sub-fasciculate, of long, cylindrical, straight or curved corallites, augmenting by gemmation which is doubtfully said to be lateral. Primary and secondary septal laminæ are present, the former spined on their free edges, the latter represented by rows of granules. The tabulæ are regular and complete; dissepiments do not exist, and no mention is made of a fossula. The affinities of this coral are believed by the author to be with *Amplexus*, but, from the clear description and figures, I have little hesitation in pronouncing it to be a *Tryplasma*. Indeed, the author also suggests an affinity with *Pholidophyllum*, but considers the length of the septal spines in his species as a point of distinction. A reference to some of Lindström's figures of *P. tubulatum*[2] will show that this possessed equally long spines.

Weissermel also afforded some interesting particulars about *Cœlophyllum*[3] and *Pholidophyllum*. He regarded the first merely as a sub-genus of *Amplexus*, following Frech, and described his *C. eurycalyx* as forming "bundle-shaped masses," the corallites varying from between short coniform to long subcylindrical, with bell-mouthed calices and everted margins, diverging from one another; fistulæ are present. The septal lamellæ are more than fifty, and of two orders; the secondary, if I understand the author correctly, are toothed. The tabulæ are complete, horizontal, and closely packed. Copious calicular gemmation takes place; the buds at first "pouch-shaped," then becoming slightly divergent slender cones, and giving to the entire colony a cluster or bundle-like appearance; there are eight buds to a calice.[4] Weissermel very justly draws attention to the close resemblance of the septal apparatus of his coral to that of *Pholidophyllum* and *Polyorophe*, Lindström. He also figures the wide expanding calice, close tabulæ occupying a stem-like corallum, and toothed free edges of some of the septal lamellæ. The resemblance between these structures and those of one of our New South Wales *Tryplasmæ*, particularly those of the calice and stem, is very marked, and will be commented on later.

Weissermel also refers to *Pholidophyllum* a composite coral,[5] composed of bundles of long cylindrical corallites in contact with each other, and

increasing by calicular gemmation. He failed to detect any opercular scales, but mentions the two conditions—specific (cone-shaped) and mutatio (cylindrical)—described by Lindström. The peripheral area between the septal lamellæ is filled with stereoplasma of varying thickness, but in some corallites forming a solid zone, which leaves only the spine-like ends of the lamellæ free.

1902.—Mr. N. Lebedew, in his "Devonian Corals of Russia," refers to Lonsdale's type *T. æquabile* as a *Cyathophyllum*,[1] but I regret my inability to read Russian and am not in a position to discuss the matter further.

[1] Lebedew—Mém. Comité Géol. Russ., 1902, XVII, No. 2, p. 87. Lebedew gives references to two other notices of *T. æquabile*, those of Grünewaldt and Hoffman.

III.—RELATION TO OTHER GENERA, AND SYSTEMATIC POSITION OF TRYPLASMA.

The family Palæocyclidæ, instituted by Dybowski,[1] contains several genera of small, simple, discoidal or bowl-shaped corals, some of which, at least, possess lamellar septa crenulated on their free edges and granulated laterally —such, for instance, are *Palæocyclus*, Ed. and H.,[2] and *Acanthocyclus*, Dybowski.[3]

Palæocyclus, according to the late Prof. P. M. Duncan,[4] possesses tabulæ, a fossula, and endothecal tissue [septal dissepiments]. In the presence of the two latter structures it therefore differs from *Tryplasma*. On the other hand, the late Prof. K. Zittel[5] says that throughout the family both tabulæ and dissepiments are wanting. *Acanthocyclus*[6] is described by Dybowski in but very few words, and really does not appear to possess any characters of importance separating it from *Palæocyclus*.

The presence of tabulæ, septal spines, radiciform processes or anchoring rootlets, and fistulæ at once distinguishes *Tryplasma* from the simple corallum of *Petraia*, Munster, as restricted by F. Roemer[7]; indeed, the septal structures are but very feebly developed at all in this genus.

From all the *Amplexus*-like forms, *Tryplasma* is separated by the presence in the latter of septal spines, although in some other points there is a close degree of resemblance. In *Amplexus* the corallites are always simple and solitary,[8] and occasionally hollow radiciform processes are developed. The septal lamellæ are remarkably rudimentary, narrow as in *Tryplasma*, but unlike those of the latter, these lamellæ, in all typical *Amplexi*, are never produced into spines on their inner or free edges; a septal fossula is present, but never in *Tryplasma*, and dissepiments exist in neither. Messrs. J. Thomson and H. A. Nicholson say[9] "there may or may not be interseptal

[9] Thomson and Nicholson—Ann. Mag. Nat. Hist., 1875, XVI (4), p. 425.

dissepiments, whilst these, when present, are always comparatively simple and few in number." Dr. Clemens Schlüter has treated this subject at length,[1] and pointed out that sundry corals possessing dissepiments have been referred to *Amplexus, e.g., A. lineatus,* A. Roemer, *A.* (*Campophyllum*) *giganteus,* Mich., &c., but as dissepiments are not present in the type species *A. coralloides,* J. Sby., their absence may be accepted as a generic character, and the genus must be restricted accordingly; the late Prof. L. G. de Koninck denied[2] the presence of dissepiments in *Amplexus.*

The tabulæ of *Amplexus* proper are exceedingly well developed, complete, either horizontal or oblique, and usually distant from one another, or sub-vesicular, forming a wide, central, usually smooth area on which the septa do not impinge to any great extent, just as we find them in the various species of *Tryplasma.* In other words, the latter, so far as its general structure is concerned, is an *Amplexus* in which the corallum is either simple or sub-fasciculate, the septal laminæ spined, without a fossula, and reproduced almost wholly by calicular gemmation. Even in *Amplexus,* budding is believed, by some Authors,[3] to take place.

The late Mr. James Thomson described[4] the septa as either wanting, or delicate and short, and of one order; a rudimentary fossula is also said to exist, "which is usually formed by a slight lateral depression of the tabulæ." All the species described by Thomson are simple, and are said to be "developed from ova." In two of the species, however, there are these peculiarities:— In *A. Sowerbyi,* Phill., "the septa are indicated by minute pointed granules," and in *A. irregularis,* the secondary septa only are so.

The community of structure between *Acanthodes,* Dybowski, and *Tryplasma* has already been pointed out.

Closely allied to *Amplexus* is *Pycnostylus,* Whiteaves.[5] The latter is said by its describer to differ from the former "only in the circumstance that it grows in colonies of compound and apparently fasciculate corallites."[6] It may also be said to differ, again according to Mr. Whiteaves, in its method of reproduction "by calicular gemmation at distant intervals into sets of three, four, or more ascending, subparallel, contiguous, flexuous branches."

[5] Whiteaves—Canadian Pal. Foss., 1884, III, Pt. 1, p. 3.

[6] Whiteaves—Canadian Pal. Foss, 1895, III, Pt. 2, p. 49.

This mode of increase is a very remarkable one, and excellent examples of it will be found in some of our illustrations of *Tryplasma* reproduction. The tabulæ of *Pycnostylus* appear to be always horizontal and complete. Were it not for the spined septal lamellæ of *Tryplasma*, the latter is, to all intents and purposes, a *Pycnostylus*.

It has already been stated, in the second section of this Memoir, that Dr. Clemens Schlüter made use of Dana's name *Calophyllum*, resuscitated by Dybowski, for a Devonian coral, which, from subsequent researches, appears to possess all the characters of *Tryplasma*. Now, *Calophyllum* has always been a stumbling-block in the path of students of Palæozoic corals. By Dana it was described[1] without type, or assigned species, as simple, caliculato-ramose or aggregate, with septa and concave tabulæ, but no dissepiments. The width of the septa was not stated, nor whether consisting of simple, vertical lamellæ, or the latter bearing spines or granules. Messrs. H. Milne-Edwards and Haime considered[2] that *Calophyllum* did not differ from *Amplexus*, and that Dana included in it very diverse forms.

Dybowski appears to have been the resuscitator of *Calophyllum*. On a previous page it was explained that he adopted the name for certain Silurian corals from the Baltic Provinces.[3] I think it may be accepted that of the two species described, the first (*Calophyllum Roemeri*) is a *Tryplasma*, although we are faced with the question of lateral budding in this instance. To obviate the difficulty caused by the halo of doubt overhanging *Calophyllum*, Dana, the late Prof. F. von Roemer proposed the name *Cœlophyllum*[4] to take its place, and as his type selected *Calophyllum paucitabulatum*, Schlüter. To the latter Author's definition, Roemer added the important statement that the radiating septal lamellæ are finely denticulated, and even delicately notched. Now, this feature, if sustained, bearing in mind the otherwise simple structure of *C. paucitabulatum*, at once places *Cœlophyllum* on a level with *Tryplasma*. The structure described by Roemer was, indeed, corroborated by Dr. F. Frech[5], who, in redescribing the same coral, says without the slightest reservation, that the septal lamellæ are notched.

It appears, however, that *Cœlophyllum* was a preoccupied name, having been used by Quenstedt for a Mesozoic coral, I believe, and certainly in 1875 by Scudder as a genus of Orthoptera.

---

[2] H. Milne-Edwards and Haime—Archiv. Mus. Hist. Nat., 1852, V, p. 347; Hist. Nat. Coral., 1860, III, p. 348.
[3] Dybowski—Mon. Zoantharia Scler. Rugosa, 1873, Pt. 1, p. 118.
[4] Roemer—Lethæa Pal., 1883, I, Lief. 2, p. 409.
[5] Frech—Dames and Keyser's Pal. Abhandlungen, 1886, III, Heft 3, p. 101.

To avoid this clashing, Schlüter in 1889 proposed *Cyathopedium*.[1] The characters of the genus are those of the type species *Calophyllum paucitabulatum*, as defined by Schlüter, who admitted the presence of denticulations on the septal lamellæ in three specimens as described by Roemer, but considered this feature formed no real distinctive character of the genus. Experience gained through the study of the Australian *Tryplasmæ* leads me to believe that the observations of Roemer and Frech are to be relied on, and *Cyathopedium* will, therefore, become a synonym of *Tryplasma*. Schlüter's original longitudinal figure[2] of *Calophyllum paucitabulatum* certainly does not exhibit any septal spines; but this possibly arises from the fact that the section from which the figure in question was prepared did not bisect a septal lamella, or pass sufficiently near the wall to show the cut ends of the septal spines. Whiteaves suggested that *Orthopedium*, Schlüter, was probably a synonym of his genus *Pycnostylus*.[3] Does he refer to *Cyathopedium*, for I cannot find a reference to any genus of the former name described by Schlüter? I think it must be so, for Schlüter, on his part, places *Pycnostylus* as a synonym of his *Cyathopedium* with a note of interrogation. If the last-named stands, and the two are identical, then Whiteaves' name has precedence.

Mr. James Thomson[4] also made use of the name *Calophyllum*, Dana, but as *Calophyllum*, according to Roemer, has no generic stability, the value of Thomson's descriptions as a contribution to the general morphology of this supposed genus are completely discounted. At the same time, some very curious Carboniferous corals were so named by this Author. They are simple cylindro-conical corals with dissepiments and a fossula, into which one or more of the primary septal laminæ protrude, and at least two of the species are described with granular secondary septa. As *Tryplasma* regularly possesses both orders of its septa constantly spined, and neither true dissepiments nor a fossula, the Carboniferous corals in question need not be mistaken for the former.

We now come to the all important consideration of *Pholidophyllum*. I have endeavoured, in previous pages, to show, and hope to do so more conclusively in those that follow, the close and intimate relation existing between the structure of *Pholidophyllum* and my conception of that of

[1] Schlüter—Abhandl. Geol. Specialkarte Preuss. Thuring. Staaten, 1889, VIII, Heft 4, p. 5 (263).

Tryplasma. Only one fundamental difference exists between ***Pholidophyllum tubulatum*** and the species I have referred to ***Tryplasma***, both Australian and exotic. In no description of any of the latter have I noticed any reference to the exothecal structures described by Lindström adhering to the outer walls, or at the edge of the calice in *P. tubulatum*, and, similarly, there is no trace of these in any of the Australian forms. These scales were regarded by Lindström as homologous with the opercula of ***Rhizophyllum*** and its allies. If, therefore, the presence of such scales is essential to the stability of ***Pholidophyllum***, and further, if ***Tryplasma***, Lonsdale, is the equivalent of Lindström's genus, then I am fain to confess that our Australian corals cannot be so referred. The whole matter hinges on the question, are these exothecal scales homologous with the opercula of ***Rhizophyllum, Calceola***, &c. ? In the well-considered words of a reviewer of Lindström's paper—"The Operculate Corals of the Palæozoic Formation"—"the walls were covered with vertical rows of regularly disposed, minute, overlapping calcareous scales or plates, oval or pear-shaped in outline, minutely striated on the outer surface, and with a small process on the inner surface as if in connection with a muscular attachment. The plates are in paired rows, each pair covering over the slight vertical furrow between two rugæ or costæ. Judging from their sections, one side of each scale seems to have been slightly embedded in the wall of the coral, but the attachment must have been slight, for examples in which these scales are preserved *in situ* are very rare." The reviewer added, "which in a certain sense are homologous with the opercula of the genera above mentioned." [1]

These lids, or "opercula" of the Palæozoic Operculate Corals, were also likened by Lindström to the opercular valves of the living genera *Primnoa* and *Paramuricea*.[2] He remarked:—"I think there exists some sort of homology to these ectodermic scales of the Primnoæ amongst the Rugosa in *Cyathophyllum* (*Pholidophyllum*, n.g.) *Loveni*, Edw. and H.,[3] specimens of this very common and widely distributed fossil show, when in a good state of preservation, a thick covering of small ($\frac{1}{2}$ mm.), very thin scales, tightly clustered together in longitudinal rows along the costæ. . . . . This position of the scales on the theca or epitheca of the coral gives them an exothecal character." [4]

---

[1] G.J.H.—Geol. Mag., 1883, X (2), p. 133.

[2] Lindström— Geol. Mag., 1871, VIII, p. 122.

[3] Later placed as a synonym of *Pholidophyllum tubulatum*.

[4] Lindström—Geol. Mag., 1871, VIII, pp. 125-26.

It is not for me even to attempt to controvert the accuracy of Lindström's description of these scales; indeed, their presence is most satisfactorily shown in one of his enlarged figures.[1] May it not be possible that Lindström, led away by the importance of his wonderful discoveries of the operculate nature of the *Goniophyllum—Rhizophyllum* group of corals, attached too much classificatory importance to the presence of these exothecal scales? It is significant that Dr. G. J. Hinde, in reviewing Lindström's great paper, said of the scales in question, as already quoted—"which, in a certain sense, are homologous with the opercula" of *Primnoa*, &c. It is equally striking that Lindström admits the absence of these scales on the outer corallite surfaces of the [sub] compound colonies. Why should they be absent? The colonies are not compound in the strict sense of the word, but sub-compound or sub-fasciculate, leaving quite sufficient space between individual corallites, here and there, for the attachment of scales.[2] If it be possible for a colony to develop its fistulæ between its component corallites, one would expect to find at least some trace of the scales also. Again, if it be the case that scales are not developed on exotic sub-compound colonies, it will explain their absence on our indigenous sub-fasciculate species. There remains the undoubted fact that, so far, no trace of exothecal scales has been observed on any of our simple forms, although very careful search has been made for them.

The structure of *Pholidophyllum tubulatum* and that of the corals here described as *Tryplasma* is so absolutely similar, it is impossible to conceive them to belong to other than one genus, notwithstanding the absence of these exothecal scales in the latter. The same may also be said of those European Silurian and Devonian corals indicated in Part II of this Monograph, such as Dybowski's *Acanthodes*, *Cyathopedium paucitabulatum*, Schlüter, *Cœlophyllum eurycalyx*, Weissermel, and sundry species of so-called *Amplexus*.

The presence of exothecal scales does not, to my mind, by any means necessitate the inclusion of *Pholidophyllum* in the "Anthozoa Operculata" of Lindström, any more than do the opercular scales of the recent genera *Primnoa* and *Paramuricea*. Indeed, Lindström did not so include *Pholidophyllum* in his own classification,[3] but contented himself by placing the description of the latter, with that of one other coral, at the end of his paper,

[1] Lindström—Bihang K. Sv. Vet-Akad. Handl., 1882, VII, No. 4, t. 5, f. 18.
[2] See Lindström's figure, *ibid.*, t. 2 f. 18.
[3] Lindström—Bihang K. Sv. Vet.-Akad. Handl., 1882, VII, No. 4, p. 10.

ruled off from the remainder, with the introductory remark quoted in the third paragraph, on p. 47. One of the principal characters of the "Anthozoa Operculata" is the highly vesicular nature of the corallum, a feature not met with in *Pholidophyllum tubulatum* any more than it is in the Australian *Tryplasmæ*, or any of the other corals here cited as probably congeneric. As a matter of fact, these are all distinguished, amongst other characters, by an entire absence of this tissue.

Again, the presence of spined septal lamellæ, or the spines represented by longitudinal rows of granules, cannot alone be accepted as distinctive of the "Anthozoa Operculata." Both these structures, wholly, or in part, are found in other corals, *e.g.*, [*Amplexus*] *Sowerbii* (Phill.), Thomson, [*A.*] *serpuloides* (De Kon.), Thomson, [*A.*] *irregularis*, Thomson, all from the Scotch Carboniferous[1]; in *Phryganophyllum Duncani*, De Kon.,[2] also Carboniferous; in *Cyathophyllum vermiculare* (Goldf.), Frech,[3] *Hallia quadripartita*, Frech,[4] and *H. callosa* (Ludwig), Frech,[5] all Devonian, whilst the pointed projections, or teeth, on the free edges of the septal lamellæ in such genera as *Heliophyllum*, *Crepidophyllum*, *Phillipsastræa*, &c., are so well known as hardly to need comment.

Reviewing the whole question dispassionately, and after giving full weight to the presence of the exothecal scales in *Pholidophyllum tubulatum*, it seems to me that more is to be gained by removing the latter, as a representative *Tryplasma*, from the vicinity of the Anthozoa Operculata, and, with other congeneric corals, placing it in a separate family, the Tryplasmidæ, with relations to *Amplexus* and *Pycnostylus*. With the two latter, *P. tubulatum* has already been shown to be closely allied in the absence of a fossula and dissepimental tissue, and the rudimentary nature of its septal apparatus.

The absence of the peripheral zone of endothecal tissue composed of dissepiments (with the possible exception of *T.* (?) *Murrayi*), so characteristic of the Order Cyathophylloidea, forbids the inclusion therein of the Tryplasmidæ. On the other hand, the Order Zaphrentoidea "comprises those corals in which there is a comparatively limited amount of dissepimental endotheca, the visceral chamber never being sheathed with a zone of vesicular tissue."[6]

Amplexus is usually associated with *Zaphrentis* in the Zaphrentoidea, but in the first instance I suggest that it be relegated to a family of its own —the Amplexidæ—with *Pycnostylus*, on account of their rudimentary septal lamellæ, the very poor development of dissepimental tissue, even when present, and by an inconstant fossula. This separation will then lead the way to the establishment of the Tryplasmidæ, characterised by the dentate or spinose free edges of the equally rudimentary peripheral lamellæ, or the reduction of the latter to mere rows of granules, and the entire absence of a fossula and also dissepiments, with the possible exception referred to above. The reproduction in the first family is sexual, or asexual by calicinal budding; in the second by parietal or calicinal budding, chiefly the latter, and mostly rejuvenescent.

In proposing the separation of *Amplexus* from the Zaphrentidæ I have, to some extent, been guided by the following remarks of Messrs. Thomson and Nicholson[1]:—"Upon the whole, therefore, these two genera [*Amplexus* and *Zaphrentis*] are marked off from one another by characters of a more fundamental and recognisable nature than those which separate *Zaphrentis* from *Cyathophyllum*."

The interseptal loculi, if they can be so called, in *Tryplasma* are usually filled with stereoplasma, as in the Hadrophyllidæ, but in that family there is a septal fossula, and the septal lamellæ are entire, but dissepiments are not present. A fossula is also present in the Palæocyclidæ, but as to the existence of tabulæ authorities differ, and as in the Tryplasmidæ, the septal lamellæ are rudimentary, and with crenulated free edges. Zittel and Nicholson refer to the absence of tabulæ and dissepiments in the Palæocyclidæ, but Duncan describes both.[2] To separate *Amplexus* from the Zaphrentidæ, and to place *Tryplasma* in a family of its own, seem to tend towards the simplification of a rather complex subject.

Lindström, in 1882,[3] made use of the name *Polyorophe* for an Upper Silurian coral. This was described as a composite coral with obovate or elliptic corallites "emitting frequent, large, broad hooks laterally, which connect adjoining polyparies"; the septa being represented by numerous lines of low, blunt spines. The tabulæ are complete, spaced, and nearly horizontal, and the epitheca quite smooth. The only other author

who has referred to this coral, so far as I can ascertain, is Weissermel,[1] who does not throw any further light on its structure or relations. It is evidently related to *Tryplasma*, but from want of knowledge I am not able to pursue the matter further.

One last point remains to be referred to. It is highly probable, as Lindström points out,[2] that some at least of the small simple corals placed in *Turbinolopsis* and *Petraia* are referable to *Tryplasma* (*Pholidophyllum*). He mentions one species, *Turbinolopsis* (*Petraia*) *bina*, Londsdale, Phillips, McCoy, &c.

IV.—GENERAL STRUCTURE[1] OF AUSTRALIAN TRYPLASMÆ.[2]

1. *Corallum or Colonies.*—The species of our *Tryplasmæ* present four types of growth. In three, *T. Lonsdalei*, and its varieties, *T. congregationis* and *T. delicatula*, the corallum is always in the form of fasciculate or subfasciculate masses of considerable size, the degree of contiguity of the corallites to one another varying considerably. In *T. Lonsdalei*, and its var. *scalariformis* the growth is loose and open, whilst in the var. *minor* it is compact. In well-grown colonies, particularly of the var. *scalariformis*, the corallites certainly radiate from one original point of growth. In *T. congregationis* the colony is composed of closely arranged corallites, or separated from one another by moderate interspaces.

The second group consists of *T. columnaris* and *T. dendroidea*. These possess a close external resemblance to some species of *Amplexus*, *e.g.*, *A. coralloides*, J. Sby., in their long, columnar outline. The resemblance is intensified on transverse fracture by the appearance of the wide tabulate area of each corallite.

The third section comprises *T. princeps*, *T. liliiformis*, and *T. derrengullenensis*. The corallites of *T. princeps*, our largest solitary species, were, in their first stage, simple, ultimately forming gemmiferous bundles of considerable size. It is probable that *T. liliiformis* must be associated with *T. princeps* in its form of growth., for I have not seen any indication that the corallites commenced their existence other than as solitary individuals ultimately becoming bunches or aggregations by repeated budding, but of a looser formation than in *T. princeps*.

The fourth and last section consists of one species, *T. wellingtonensis* in which the corallite, at first simple and solitary, by repeated single calicinal gemmation, gave rise to a chain of individuals, more or less retaining the habit of the parent corallite.

---

[1] Throughout Parts IV and V the following special terms need definition :—

Radiciform processes.—Exothecal processes used as anchoring rootlets.
Fistulæ.—Exothecal hollow tubes uniting contiguous corallites.
Bourrelets.—Circumferential swellings on the corallites, representing growth periods or the edges of old calices.
Costæ.—Longitudinal exothecal ribs, or ridges, corresponding to primary septal lamellæ.
Rugæ.—Longitudinal exothecal ribs, or ridges, corresponding to secondary septal lamellæ.
Septal lamellæ.—Initial continuous laminæ of the septal apparatus, extending from top to bottom of the corallites.
Septal spines.—Denticles or spines forming the free inner or distal edges of the septal lamellæ.

[2] Omitting from consideration that of *T.* (?) *Murrayi*.

The mode of growth merely,[1] in one section of this genus, typified by *T. Lonsdalei*, recalls that of several well-known genera of Cyathophyllidæ, such as the fasciculate species of *Lithostrotion*, *Diphyphyllum*, *Cylindrophyllum*, &c. The nature of the septal apparatus, however, absence of dissepimental tissue and septal loculi, or any form of peripheral tissue whatever, and the want of a fossula, will, on more attentive examination, at once distinguish the members of this section from these and their allies.

2. *Corallites.*—In the sub-fasciculate species, and in *T. vermiformis*, the corallites are always long, generally slender, and cylindrical, straight or slightly flexuous, and gradually increasing in size upwards, round or oval. The greatest length yet measured of one of these corallites is six inches, the diameter varying from five to fifteen millimetres. The corallites of *T. Lonsdalei* var. *minor* are uniformly of the least diameter, five millimetres, those of *T. Lonsdalei* proper, the next in progression, from six to eight millimetres; those of the var. *scalariformis* six to ten, and even reaching to fifteen millimetres at points in their courses immediately preceding gemmiferous bifurcation, and imparting to such corallites a stronger and much more robust appearance; the largest are those of *T. congregationis*, in which the normal diameter varies between ten and fifteen millimetres. The corallites are free during some portion of their course, and here and there united laterally by their walls, or by cylindrical fistulæ. In *T. congregationis* a larger proportion of the corallites appear to be united laterally than in the other species, and the fistulæ are here developed to their greatest extent; the corallites of this species are also noticeable from a less regular longitudinal outline, frequently enlarging and contracting in diameter.

Long cylindrical corallites are again met with in *T. columnaris* and *T. dendroidea*, and in both are either straight, with a characteristically pipe-like appearance, or slightly flexuous for short distances. With the ultimate form of growth of *T. columnaris* we are not acquainted, but in *T. dendroidea* budding probably brought about an open shrub-like corallum; the former attains the largest diameter of any of the cylindrical species, from fifteen to twenty-five millimetres.

In the following species the early stage was simple, cylindro-ob-conical, or turbinate, retaining this form until the first gemmation took place. The cylindro-ob-conical type is seen in its fullest extent in *T. princeps*, which is also the largest species of this section of the genus. The large, stout corallites

[1] Omitting the fistulæ from consideration.

are either straight, or slightly curved, retaining the same diameter for some distance, or expanding slowly upwards; in this condition of the corallum the resemblance to such corals as *Cyathophyllum giganteum*, Mich., is very marked; by copious budding large bunches of corallites are formed. The turbinate outline is seen in the earlier stages of each corallite in *T. wellingtonensis*, then passing into a more irregularly cylindrical condition, often twisted, or even slightly contorted. In *T. princeps* the base is pointed, but in the previous form it may be in the same condition, or somewhat expanded; in both the section is circular or oval, the diameter of *T. princeps* attaining two and a half inches, but that of its fellow is far less. The corallites of the former vary in length, but are known to extend to eleven inches, those of *T. wellingtonensis* being comparatively short at first, but by repeated gemmation forming a line of individuals four inches, and probably more, in length. Ob-conical to cylindrical corallites also characterise *T. derrengullenensis*, and may become twisted or contorted; this species bears the distinction of presenting the greatest outward resemblance to *T.* (*Pholidophyllum*) *tubulatum*.

In *T. liliiformis* the corallites are liliaceous in outline—*i.e.*, there is a stalk or stem-like portion below, resembling a non-budded corallite of *T. dendroidea*, varying much in length, and expanding above into wide bell-mouthed calices, as much as three inches in diameter. As a rule these corallites are erect, but are sometimes diverted to one side or the other, although not contorted.

3. *Wall.*—In all these corals the wall proper must have been thin and delicate. More often than not fossilisation has removed it, but when present the wall is always represented by a thin, dark circle supported inwardly by a zone of secondary deposit of variable thickness. In some instances the bases of the septal lamellæ are distinctly traceable to this thin theca, and it may, in consequence, be justly concluded that this latter is formed by the confluent bases of the septal lamellæ.

4. *Epitheca.*—I am but imperfectly acquainted with the nature of this investment; it is seldom preserved, and if so, only indifferently. So far as one can see, it consisted of a thin layer of tissue concentrically lined, the strength and distance apart of the threads varying according to species. This epithecal layer also clothed the radiciform processes and fistulæ.

5. *Exothecal Scales.*—No trace whatever of these much debated scales, first noticed by Lindström, and compared by him to the opercula of *Primnoa*,

and by analogy to those of the Palæozoic Operculata, has been detected. So many specimens have now been examined, upwards of three hundred, that had these structures existed some trace must have come under notice.

6. *Bourrelets or Accretion Swellings.*—Throughout the Australian *Tryplasmæ* the bourrelets do not form an important feature. In *T. Lonsdalei* these swellings were very slight; in *T. vermiformis* represented by delicate, equal, rounded rings, closely following one another. In *T. congregationis* and *T. columnaris* they are irregularly developed, and are stronger and more projecting than in any of the other species, with the exception of one doubtful example (Pl. XVII, fig. 6) of *T. princeps.* In some instances, at any rate, these represent the margins or edges of old calices. I believe this to be the case in *T. wellingtonensis.*

7. *Radiciform Processes.*—These are tubular prolongations of a corallite wall, and were used as anchoring filaments, single or in clusters. In some the tubular or hollow nature is very apparent (Pl. XXII, fig. 10), accompanied by a stereoplasmic thickening arranged in concentric layers. They have not been observed in all species, particularly the sub-fasciculate forms, but in *T. princeps* are very noticeable, especially towards the bases of the corallites, although they do occur at all heights. Radiciform processes are also met with in *T. wellingtonensis,* but sparingly so, both towards the bases of the corallites and around the exterior of the calice margins. They occupy the same positions in *T. liliiformis,* but in contradistinction to *T. wellingtonensis,* were well developed, and of considerable length.

These anchoring stolons are quite as well developed in *T. princeps* and *T. liliiformis* as they are in the genus *Omphyma* (*e.g., O. subturbinata,* D'Orb.). If Nicholson's statement that the rootlets in this genus are simply exothecal structures is correct,[1] then a marked difference exists between the latter and the radiciform processes of *Tryplasma,* which are, as already explained, prolongations of the general visceral cavity of the coral. Specimens of *O. subturbinata* in the Australian Museum collection certainly appear to me to possess hollow processes.

Lindström records the interesting fact that radiciform processes "distinguish no less than eleven genera of the *Cyathophyllidæ.*"[2] He explained their formation as follows:—"The membrane which lined and secreted the walls of the calyx then formed small branches, which also

[1] Nicholson—Man. Pal., 3rd Edit., 1889, I, p. 288.
[2] Lindström—Geol. Mag., 1866, III, p. 358, f.n. 1.

secreted calcareous matter around themselves, and thus formed these root-like tubes."[1] In all probability these radiciform processes are hollow and tubular throughout the whole of the Cyathophylloidea, and not exothecal. Lindström has also demonstrated the presence of such anchoring filaments connected with the interior of the calices in some of the Operculata, such as *Rhizophyllum gotlandicum*, *R. elongatum*, and possibly in *Goniophyllum*; in *R. elongatum* these tubes are tabulate,[2] and in *R. attenuatum* become actually stoloniferous, giving rise to new corallites.[3]

In some cylindrical or conical corals these radiciform processes are developed on all sides of the corallite, but in others only on one; in the latter case this probably represents the underside, or that to which the corallite is inclined.

8. *Fistulæ*.—These are present in two of the three sub-fasciculate species and one of the ob-conical forms, forming a prominent feature in *T. Lonsdalei*, even more so than in its two varieties, and are present in all parts of the corallum, but placed at irregular distances from one another. It is in *T. congregationis* that these connecting processes are seen in their fullest development at regular stated intervals between corallites, tier above tier. The young corallites, or buds, in *T. princeps* are united by fistulæ—a very interesting point in the morphology of these corals.

The processes are more or less horizontal, usually swollen at their points of projection from the corallites, diminishing in diameter in their median course. They are tubular, and, like the radiciform processes, are not only prolongations of the visceral cavities of the corallites they unite, but are partially filled with concentric stereoplasma. In *T. Lonsdalei* the septal spines continue quite into the mouths of the fistulæ, and in one instance a spine was observed in the open tube course (Pl. XXVI, fig. 7).

The presence of fistulæ in *Tryplasma* recalls the structure of the *Eridophyllum* group on the one hand, and the systematically distant *Syringopora* on the other. There is, however, this difference between the fistulæ of *Tryplasma* and the processes connecting the corallites in *Eridophyllum*—that, whilst the fistulæ in the former are projected indiscriminately from all sides of a corallite, there does seem to be a marked protrusion of processes from one side only of each corallite in a given corallum

[1] Lindström—Geol. Mag., 1866, III, p. 406.
[2] Lindström—Bihang K. Sv. Vet.-Akad. Handl., 1882, VII, No. 4, t. 2, f. 15 and 16.
[3] Lindström—Bihang K. Sv. Vet.-Akad. Handl., 1882, VII, No. 4, t. 3, f. 17.

in the latter.[1] On the other hand, the arrangement in *Syringopora* agrees with that of *Tryplasma*, and, like the latter, the fistulæ of the former are hollow and extensions of the visceral cavities; but the processes in *Eridophyllum* proper "are not connected with the interior of the coral."[2] In one species of *Eridophyllum* (*E. simcoense*, Bill.), Rominger has already noticed the resemblance to *Syringopora*. In describing the last-named coral as a *Diphyphyllum*,[3] he says:—"The stems laterally connect by slender, transverse processes, similar to the transverse tubules of *Syringopora*—not, however, making communication between the visceral cavities, as in those, but merely fastening externally to the walls for mutual support."

This coral has been placed by Mr. G. B. Simpson in a new genus, *Synaptophyllum*, the connecting processes proceeding from all sides of a corallite, the expansions of adjacent corallites opposite, hollow, and meeting and coalescing midway between, but intercommunication cut off by a partition formed of the wall of one of the processes. Connecting processes also occur in *Schœnophyllum*, Simpson, and *Placophyllum*, Simpson.[4]

9. *Rugæ*, or *Pseudocostæ*.—Costæ are not present in the Australian *Tryplasmæ*, but the vertical, more or less parallel ridges traversing the exterior of the corallites from top to bottom, correspond to the secondary septal lamellæ, and not to the primary; in consequence of this, they are probably more nearly allied to rugæ or pseudocostæ. They appear to be the exothecal edges of the secondary septal lamellæ, as the costæ are those of the primary in other corals, and do not call for any special remark, except that neither granules nor teeth, or other special ornamentation, have been seen on them.

10. *Calices*.—In the few instances in which the calice is known, it has always proved to be deep, and in its lower course straight-walled. The calices of *T. princeps*, *T. wellingtonensis*, *T. derrengullenensis*, and *T. liliiformis* fulfil these conditions; but in the last-named the upper portion expands into a wide bell-mouth cavity, with a flange-like periphery. The floor may be either concave, oblique, or rolling, sometimes horizontal, and is formed by the uppermost tabula, on to which the septal spines project more or less, according to species.

[4] Simpson—Bull. N. York State Mus., 1900, VIII, No. 39, pp. 214-16.

11. *Septal Lamellæ and Spines.*—We may now consider the most important feature of this group of corals—the structure of the septal apparatus. This consists primarily of narrow longitudinal lamellæ, extending from top to bottom of every corallite, and which spring from the theca as in other sclerodermic corals; and secondly, the distal or inward edges of these lamellæ are broken up into spines of greater or less length, but never attaining any great degree of length; the septal apparatus may, therefore, be described generally as marginal or peripheral. This feature is common to and constant throughout the whole group, varying only in degree specifically. There is a decided, although at times slight, difference in length of these spines in alternate rows, indicating the presence of primary and secondary lamellæ, the secondary spines being occasionally reduced to mere granules on the free edges of the lamellæ. The spines, thorn-like projections, invariably point upwards obliquely in the direction of growth of the coral, and form a good index for determining the upper and lower surfaces of a colony when this is not otherwise apparent; horizontal spines are here and there present also, as well as laterally curved, but these cannot be regarded as other than occasional. The number of cycles in an intertabular space does not appear to follow any constant rule, these cycles varying from one to four, and in some cases more. In *T.* (*Acanthodes*) *tubulum*, Dyb., and *T.* (*Acanthodes*) *rhizophorus*, Dyb., four cycles occur, but in *T.* (*Acanthodes*) *cylindrica*, Dyb., there appears to be only one.

The septal spines are neither tubular nor hollow, although so described by Lonsdale and Dybowski. Von Koch says that the central line [primordial septum] in each is dark coloured in *T.* (*Pholidophyllum*) *Loveni*, Ed. and H.,[1] and this is frequently to be seen in sections of our species.

In transverse sections prepared for the microscope, the septal spines often appear much broken up, and dot like—this is due to the section cutting the upwardly projecting spines of more than one cycle. Similarly, when a longitudinal section is cut eccentrically and close to some portion of the corallite wall, the same cut ends again appear as so many vertical lines of disconnected dots.

The lamellæ in *T. Lonsdalei* and *T. princeps* are very narrow, and purely marginal in *T. wellingtonensis* and *T. liliiformis*; they are stout and strong in *T. princeps*, but very delicate in *T. congregationis*. The separation into primary and secondary is distinctly marked in *T. Lonsdalei* and *T.*

[1] Weissermel—Zeitsch. Deuts. Geol. Gesellsch., 1894, XLVI, Heft 3, p. 640.

vermiformis, but most so in *T. wellingtonensis*. On the other hand, there is hardly any distinction between the two orders in *T. congregationis*, whilst in *T. princeps* and *T. columnaris* the amount of disparity is variable. The two extremes in number to a cycle lie between *T. vermiformis* with twenty-eight, and *T. delicatula* with thirty-three, to *T. columnaris*, *T. liliiformis*, and *T. princeps* with eighty. As regards typical development, *T. Lonsdalei* presents the best example.

The primary spines are longest in the species first mentioned and in *T. wellingtonensis*, in which they extend into the visceral chambers for at least one-third of the diameter of the latter; they are long and tapering in *T. columnaris*, very short in *T. congregationis* and *T. liliiformis*, and delicate in the last species but one. The secondary spines are very short in *T. vermiformis*, and reduced to mere granules in *T. wellingtonensis*.

The direction is, as a rule, obliquely upward, although in the last-named species and *T. liliiformis* horizontal spines have been detected, and in *T. princeps* there are some laterally curved. In *T. Lonsdalei* some of the spines are laterally denticulated, and in *T. derrengullenensis* there appear to be more cycles of secondary lamellæ than primary in a given space, at any rate in the calice.

Septal lamellæ spined on the distal or free edges are by no means unknown in genera of Cyathophylloidea—for instance, in the Heliophyllidæ they occur as transverse ridges or teeth, *e.g.*, *H. arachne*, Hall.[1] Passing to the Zaphrentoidea we meet with the curious little *Palæocyclus* (if this genus is correctly referred to this order), in which the free edges of the lamellæ are strongly echinulate. Moreover, in *Heliophyllum* and in some species of *Phillipsastræa* the lamellæ are provided with lateral carinæ, *i.e.*, oblique lamellar ridges directed inwards and upwards, which Nicholson compared[2] to the septal spines of *Tryplasma* (*Pholidophyllum*), and by analogy they may be equally compared to the lateral denticles on the spines in *T. Lonsdalei*. In all the corals mentioned there is this manifest difference—that whilst in them the lamellæ extend to the centre of each corallite, and are therefore true septa, in the *Tryplasmæ* they are simply peripheral.

In contemplating the septal apparatus of *Tryplasma*, it is impossible to divest one's mind of the strong resemblance of the spines to those of some

[1] Hall—Ill. Dev. Fossils: Corals Up. Helderberg and Hamilton Groups, 1876, t. 24, f. 10.
[2] Nicholson—Man. Pal., 3rd Edit., 1889, I, p. 289.

Favosites. By this I do not mean to infer any systematic relation between the two groups, but simply a connection in the light of comparative morphology.

A few words on the septal lamellæ and spines of the Operculate Corals (Calceolidæ) will not be out of place. In these corals the septal apparatus is incomplete and rudimentary, or even obsolete; in *Goniophyllum* and *Calceola*, although marginal, it is truly lamellar; in *Rhizophyllum* there are septal striæ; in *Arœopoma*, these are again reduced to lines of tubercles. On the whole, therefore, the septal characters of *Tryplasma* do not entirely agree with those of the Operculate Corals any more than they do with any other group of the Rugosa.

In the historical portion of this Memoir, I referred at some length to the supposed existence of canals traversing the wall, as described by Lonsdale, and showed these to be nothing more than cavities left by the removed septal spines. In by far the greater number of instances our *Tryplasmæ* are met with in the decorticated state—devoid of the theca—which has been worn off either during or subsequent to fossilisation. If this form of disintegration is carried sufficiently far to remove the septal lamellæ also, one or the other of the following conditions is apparent:—*a*, The remaining portion of the corallite is traversed by longitudinal rows of circular dots, which are the fractured bases of the septal spines; *b*, or by holes instead of dots, leading to short tubuli, which are simply moulds left by the dissolved spines. Many beautiful examples of these are in our collections, and in the case of the tubuli none better need be referred to than the small example of *T. derrengullenensis* (Pl. XXII, figs. 6 and 7), in the calice cast of which are several cycles of "canals." In species possessing differentiatedprimary and secondary lamellæ, the lines of pits will always be found to be larger and smaller alternately.

12. *Loculi*.—In consequence of the narrowness of the lamellæ septal loculi do not exist (even in *T.* (?) *Murrayi*), the short interspaces between the bases of the lamellæ being invariably filled with a secondary deposit, leaving the spines only free.

13. *Dissepiments*.—The remarks made in the last paragraph naturally prepare one for the absence of any endothecal tissue of the nature of dissepiments. So far no satisfactory evidence of their presence exists, with the sole exception of *T.* (?) *Murrayi*, which will be referred to later on; at any rate, certainly not in the subfasciculate species. On first describing *T.*

wellingtonensis[1], I wrote as follows when speaking of an intra-marginal ring in some of the corallites :—" It is, in all probability, not formed by a series of dissepiments in a single line, but is the primitive theca in the substance of the outer investment, and septa traversing this zone have an intra and extra thecal portion. In a rather more complete section (Pl. XXI, Figs. 11 and 12) an inner ring is visible which might be taken for a further series of dissepiments; it is, however, a second corallite springing from within the outer one." I have not seen any reasons to alter this view.

The almost total absence of dissepimental tissue at once recalls to mind the genera *Amplexus* and *Pycnostylus*, and a number of other Rugose genera with complete septal lamellæ[2].

14. *Tabulæ*.—One of the most conspicuous features of the corallum in all the species. The distance apart of these floors is of too variable a nature to be a reliable factor in specific description, except in one or two instances. In a comparative sense the tabulæ may be either distant or much crowded together, and in one species (*T. Lonsdalei*) this crowding occurs in clusters so constantly as to become of specific importance. The tabulæ are both complete and incomplete in all but one species, the complete often largely predominating over the incomplete. The complete tabulæ extend entirely across the corallites, from wall to wall, and may be either horizontal, concave, oblique, convex, or rolling, and more than one of these characters may be common to a species.

In the descriptions of two of the already known species (*T. wellingtonensis* and *T. Lonsdalei*), I questioned the actual union of the complete tabulæ with the corallite walls, but I am now convinced that a union is the case invariably. Dybowski described the tabulæ as ceasing at the inner or distal ends of the septal spines without reaching the proper wall; but he was probably misled, like myself, by deceptive appearances. He accounted for this, however, on the supposition that the spines are too closely packed to permit of the floors joining the wall, but it is now quite evident to me that the latter had a connection with the wall of their corallite as a support.

The incomplete tabulæ invariably give rise to a vesicular tissue, but this must not be confounded with the general vesicular structure of the Cystiphylloidea, particularly that of the operculate division; and herein lies one of the fundamental differences between this group and the

[1] Etheridge—Rec. Geol. Survey N. S. Wales, 1895, IV, Pt. 4, p. 162.
[2] *See* Sherzer—American Geol., 1891, VII, No. 5, pp. 281, 287.

Operculata. In the present instance, it arises from the inosculation of the tabulæ with one another, giving rise to triangular and wedge-shaped or lenticular vesicles, but not blister-like or sub-globular as in *Cystiphyllum* and its allies. The wedge-shaped vesicles are usually marginal, short, and sometimes deep, the lenticular more often occupying the centre of a corallite. In every corallite in which these vesicular tabulæ are a feature, there is always a certain number of complete floors, and no case of a corallite's visceral chamber filled with the vesicular type alone has come under notice. In the Operculata in particular, the interior structure of the corallites is wholly composed of true endothecal vesicles. Such is the case in *Goniophyllum*, *Rhizophyllum*, and *Aræopoma*, whilst *Calceola* so far differs that the internal structure is dense, but at the same time very finely vesicular. In one species of *Tryplasma* (*T. vermiformis*), vesicular tabulæ have not been observed.

In fractured or weathered horizontal sections, the peripheries of the complete tabulæ often present a series of short depressions or nicks, which are the imprints of the septal spines resting on them. In three species—*T. columnaris*, *T. derrengullenensis*, and *T. delicatula*—a very interesting feature was discovered in the presence of upstanding spines scattered over the upper surfaces of the floors; these are placed irregularly, or arranged in groups. In transverse sections prepared for the microscope, these appear as dark spots, or as dark rings with a refractive centre, and in either case often surrounded by a concentric secondary thickening. A similar structure was observed by Lindström in his *Pholidophyllum tubulatum*.

Oblique complete tabulæ appear to be absent in *T. vermiformis*, and possibly in *T. liliiformis* also, but are present in the other species; rolling tabulæ are met with in *T. Lonsdalei*, *T. congregationis*, *T. columnaris*, *T. princeps*, *T. wellingtonensis*, and occasionally in *T. liliiformis*; typical concave floors are to be seen in *T. Lonsdalei* and *T. liliiformis*, and those with an upward convexity in *T. congregationis*. Marginal vesicular tabulæ are present in *T. Lonsdalei*, elongately lenticular in *T. congregationis*, both conditions in *T. columnaris* and *T. princeps*, and irregular lenticular vesicles in *T. wellingtonensis* and *T. liliiformis*.

The wide tabulate non-septate area of *Tryplasma* again calls to mind the structure of the non-dissepimental genera *Amplexus* and *Pycnostylus*.

15. *Fossula*.—I cannot detect any trace of a septal fossula in *Tryplasma*; my observation is, therefore, in accord with Dr. Lindström's description of *Pholidophyllum*. In the complete horizontal, oblique, or rolling tabulæ of

T. Lonsdalei and *T. delicatula* a small central or eccentric depression or pit is often to be seen, but it has no connection with the septal lamellæ, and cannot be regarded as representing a fossula.

On the other hand, Mr. Rudolph Ludwig figured as *Zaphrentis caudata*,[1] a coral from the German Devonian, with the most unmistakable septal characters of *Tryplasma*, and, in addition, a large fossula. For this and cognate species, Mr. A. F. Foerste has suggested the name of *Palæocyathus*,[2] and includes in it an Australian coral, *Cyathophyllum australe*, Foerste,[3] common in the Bowning beds, and which certainly is not a *Tryplasma*. It may possibly be, therefore, that *Palæocyathus* will prove a convenient resting place for *Tryplasma*-like forms with a fossula.

16. *Gemmation.*—Lonsdale described the budding of *Tryplasma* as parietal, "chiefly from the sides of the parent stem"; Dybowski said the gemmation of his *Acanthodes* was parietal also, and gave a figure[4] of *A. tubulus* in which it appears to be so, but at the same time mentioning its rarity. On the other hand, Lindström refers to that of *Pholidophyllum* as calicular. In my first description of *T. Lonsdalei* I favoured the view of Lonsdale and Dybowski, and believed I had detected a few instances of parietal budding in specimens from Hatton's Corner, near Yass.[5] In the blocks of sub-fasciculate corallites from this locality it is very difficult to say exactly of what nature the budding is, but in a more recently collected specimen from a continuation of the same bed at Humewood, near Yass, it is so unquestionably calicular that I feel compelled to abandon my preconceived idea of the method in this species, more particularly as the var. *scalariformis* exhibits similar budding (Pl. XXVI, figs. 8–10).

In *T. Lonsdalei*, therefore, two buds arise from the parent calice (Pl. X, fig. 3), and immediately diverge from one another, but in the variety previously mentioned the young corallites are united laterally for some distance before diverging (Pl. XII, fig. 2). In *T. congregationis* two buds are present on one specimen (Pl. XIII, fig. 1), united only for a short distance, and then bending outwards. In *T. liliiformis* two to three young corallites arise from within the mature expanded cup. The gemmation is single in *T. wellingtonensis*, so far as known, the new corallite either continuing its upward course from an attenuated base, or at once filling the parent calice.

[5] Etheridge—Rec. Geol. Survey N. S. Wales, 1890, X, Pt. 1, p. 19.

It is, however, in *T. princeps* that gemmation is seen in its most vigorous aspect. A series of buds, in one case as many as thirteen (Pl. XIX, fig. 2) arise around the inner edge of the calice of the completed single corallum, and in their turn become well-developed corals, forming a proliferous sub-compound cluster. A similar form of increase is met with in *T.* (*Cœlophyllum*) *eurycalyx*, Weissm.[1] Even in so small a form as *T. derrengullenensis* four buds are attached to one calice; budding seems to have commenced at a very early stage in this species.

In *T. vermiformis* there are two or four buds, which curve outwardly from the parent. In the case of four, reproduction is exactly similar to that of Whiteaves' *Pycnostylus guelphensis*,[2] four equal buds usually occupying the whole of the interior of the parent calice, and each deltoid-triangular in sectional outline; this resemblance is very remarkable. Increase in *T. dendroidea* is by two to four large vigorous buds, which soon diverge from the parent stem (Pl. XIV, fig. 1; Pl. XV, fig. 5).

In a remarkably interesting paper "On the Mode of Growth and Increase amongst the Corals of the Palæozoic Period,"[3] the late Prof. H. A. Nicholson subdivided gemmation, or increase, under five heads, viz.:—

1. Simple calicular gemmation.
2. Compound calicular gemmation.
3. Parietal or lateral gemmation.
4. Basal gemmation.
5. Fission.

Gemmation in the Australian *Tryplasmæ* is confined to Sections 1 and 2, and possibly 3, and the species group themselves as follows:—

Section 1.—*T. wellingtonensis* and possibly *T.* (?) *Murrayi*.

Section 2.—The remainder, with the exception of *T. delicatula* and *T. columnaris*, in which the budding is unknown.

Dr. Lindström drew attention to a very interesting point in the growth of new calices within the old ones in the Zoantharia Rugosa,[4] and which is not, strictly speaking, true calicinal budding. He instanced a specimen of *Goniophyllum pyramidale*, His., in which a new coral was formed within the calice of an older individual, and partly so of the old walls of the latter.

[1] Weissermel—Zeitssch. Deuts. Geol. Gesellsch., 1894, XLVI, Heft 3, p. 636, f. 1 and 2.

[2] Whiteaves—Canadian Pal. Foss., 1884, II, Pt. 1, t. 1, f. 1*b*; Lambe—Contrib. Canadian Pal., 1901, IV, Pt. 2, t. 10, f. 4, 4*a*.

[3] Nicholson—Trans. R. Soc. Edinb., XXIV, pp. 237-243.

[4] Lindström—Geol. Mag., 1866, III, p. 360.

"It is very evident," he says, "that no new individual is here formed by means of budding, as the calyx and the walls are quite the same as before, with the exception of that corner" representing the new corallite. "This peculiar formation of a new calyx within the old is common to almost all individuals of *Z. rugosa*, and is repeated several times by the same individual"; Lindström cites as an example the genus *Chonophyllum*. To this method of continuity of the species Nicholson applied the term "rejuvenescence," and said:—"On this view the original polype undergoes periodic contraction and partial death, only the central part of the animal retaining its vitality. Each period of contraction is, however, followed by one of active growth."[1] No finer example of this can be adduced than Schlüter's figure of the budding of *Cyathopedium paucitabulatum*.[2] On the other hand, in true calicular budding the original polype throws up from its calicinal disc one or more new corallites, which kill the parent completely; of this condition a good example may be found in the Carboniferous *Lonsdaleia rugosa*.

This rejuvenescent calicular gemmation has been excellently figured by Von Koch, as already explained, in *T.* (*Pholidophyllum*) *tubulatum*; by Weissermel in *T.* (*Cœlophyllum*) *eurycalyx*[3]; and by Lindström in *Rhizophyllum elongatum*.[4] How extensively it is developed in our Australian *Tryplasmæ* the accompanying plates will show.

In the light of *Tryplasma tubulus*, Dybowski, it is quite possible that parietal budding occurs in the genus as the exception and not the rule; the former's sectional figure of this species certainly does appear to show two lateral buds.

17. *Geological Range.*—The whole of the Australian *Tryplasmæ* are of Upper Silurian age, no satisfactory evidence having yet come to hand of the occurrence of the genus in our Devonian rocks.

18. *Species.*—The following are the Australian species:—

Tryplasma columnaris, sp. nov.		*Tryplasma Lonsdalei*, Eth. fil.	
,,	*congregationis*, sp. nov.	,,	*princeps*, sp. nov.
,,	*delicatula* ,,	,,	*vermiformis* ,,
,,	*dendroidea* ,,	,,	*wellingtonensis*, Eth. fil.,
,,	*derrengullenensis* ,,	,,	(?) *Murrayi* ,,
,,	*liliiformis* ,,		

with two varieties of *T. Lonsdalei*, and two doubtful forms.

Cœlophyllum, Weissermel, Zeitsch. Deuts. Geol. Gesellsch., 1894, XLVI, Heft 3, p. 634.

Pholidophyllum, Weissermel, *Ibid.*, p. 638.

Generic Characters (*emend.*).—Corallum simple, sub-compound, or sub-fasciculate. Corallites turbinate, cylindro-ob-conical, or simply cylindrical. Epitheca complete and concentrically lined, but not strongly developed. Wall always thin primordially, subsequently thickened with stereoplasma. Exothecal outgrowths consist of tubular radiciform processes, fistulæ, and "scales." Costæ absent, but rugæ always present, although never conspicuous. Bourrelets poorly developed. Septal apparatus strictly peripheral, of narrow, longitudinal, more or less parallel lamellæ, supporting free, upwardly-directed spines on their distal edges, and which may or may not be granulated laterally. Septal loculi, true dissepiments, and fossula absent. Calices where known, deep, and straight-walled within, or straight-walled below, and bell-mouthed above. Tabulæ complete or incomplete, very copiously developed; complete, extending entirely across the visceral chamber, and, in consequence of the brevity of the septal lamellæ occupying the greater portion of a visceral chamber, horizontal or variously inclined,

sometimes rolling; incomplete give rise to lenticular or wedge-shaped vesicles, true blister-cysts absent; tabulæ may, or may not, support longitudinal spines on their upper surfaces. Gemmation where known copious, simple or compound-calicular, and frequently rejuvenescent; possibly also parietal.

Tryplasma Lonsdalei, *Eth. fil.*

(Plate X; Pl. XI, Figs. 2–4; Pl. XII, Fig. 1; Pl. XIX, Fig. 4; Pl. XXV, Fig. 5; Pl. XXVI, Figs. 1–7.)

Tryplasma Lonsdalei, Eth. fil., Rec. Geol. Survey N. S. Wales, 1890, II, Pt. 1, p. 15, t. 1.

Specific Characters.—Corallum of loosely aggregated to sub-fasciculate groups of corallites, sometimes forming large colonies, at least six inches in height. Corallites long, slightly flexuous, cylindrical, gradually increasing in size upwards to an average diameter of six millimetres, but attaining as much as eight, here and there united laterally either by fusion of their walls, or by fistulæ; bases pointed; length at least six inches. Epitheca delicate, concentrically lined, the lines crenulated on passing over the rugæ. Fistulæ well developed, usually more or less horizontal, present in all parts of the corallum, and only rarely passing from corallite to corallite on the same level; swollen at their junction with the corallites, and at times provided with a few septal spines; semi-fistulæ as knobs or small disconnected processes. Septal lamellæ narrow, forty to fifty in a cycle, primary and secondary; spines thorn-like, long, projecting inwards for about one-third the diameter of a corallite, from one to four cycles between tabulæ, but more commonly three, sometimes with lateral denticles. Tabulæ numerous and usually complete, generally regularly spaced apart, but here and there groups of close set floors, horizontal, oblique, or concave, often displaying a slight, central depression; incomplete vesicular tabulæ rare, but when present small, triangular and usually marginal. Gemmation compound-calicular-rejuvenescent, two buds immediately diverging from one another.

Observations.—This species must be regarded as the Australian type, as it was first described. It need not be mistaken for any other species except *T. vermiformis*; the distinctive features are referred to under the latter. The specific points of importance in *T. Lonsdalei* are:—

(1) Form of the corallum.
(2) Frequent occurrence and length of the fistulæ.
(3) Abundance of the septal lamellæ, size of the spines, and presence of lateral denticles.
(4) Grouping of the tabulæ.

The corallum is a large, sub-fasciculate and loose aggregation of long cylindrical corallites, either united by their lateral surfaces, or free and connected by fistulæ, which are seldom on the same level in contiguous tubes, although occasionally so. These fistulæ are enlarged at their junctions with the corallites, but contracted in their middle course, and do not appear to have any particular direction of curvature, although the horizontal predominates.

The corallites vary much in diameter, with eight milimetres as the approximate maximum width, and they are always wider at the offshoot of a fistula. Incomplete colonies only have been examined, but the corallites are known, even in their incomplete state, to attain six inches in length.

In my first description of this coral, I said regular accretion rings or bourrelets were absent. This was, however, an error; they are present in some examples, but weak and inequidistant.

The septal spines are highly developed and acicular, and the difference in size at once indicates the presence of primary and secondary lamellæ; lateral denticles are sometimes present.

The tabulæ are a very conspicuous feature in *T. Lonsdalei*, and are numerous in every corallite, the complete predominating largely over the incomplete. The clusters of closely packed tabulæ are a noteworthy and interesting detail. This is one of the forms with occasional depressions on the upper surfaces of the tabulæ, usually central, but sometimes excentric and then lateral; as I have already explained, these depressions are in no way of the nature of a fossula. Vesicular tabulæ do occur in *T. Lonsdalei*, but are small, marginal, and triangular in longitudinal section. The complete tabulæ immediately below a gemmiferous bifurcation are distinctly sigmoidal, and, adopting a term from Crinoid terminology, may be termed axillary. Oblique floors are not common as a rule, but one instance has come under notice in which the whole of them in five corallites, forming the section, are oblique, or oblique and rolling, or oblique and convex.

Gemmation has been observed but in few instances. The budding is certainly calicular, and may perhaps be parietal also; so far as I can ascertain, two buds only are given off from a parent corallite, and not four as in *T. dendroidea* and *T. vermiformis*; these branch obliquely from the parent, and present the appearance of a bifurcating stem. A specimen from the Sydney University collection exhibits a double bifurcation in the space of two and a quarter inches. It is possible that both parietal and calicinal gemmation

may occur in *T. Lonsdalei*, although I have not clearly seen the former. Nicholson says that in some cases compound calicular gemmation gives rise to fasciculate colonies,[1] and cites the Silurian *Cyathophyllum articulatum*, Wahl.,[2] as a case in point. "This peculiarity," he says, "is partly due to the fact that the secondary corallites remain cylindrical, without expanding materially; that they rise side by side without uniting, and without greatly diverging; and that their vertical growth is continued for a considerable period before they in turn give rise to calicine buds. Another cause for their fasciculate form is, however, to be found in the fact that in these cases true parietal gemmation is often combined with true calicinal budding."

The relation of *T. Lonsdalei* to *T. vermiformis* and *T. delicatula* is referred to in the descriptions of the latter species. Although *T.* (?) *Murrayi*, mihi.,[3] appears to be sub-fasciculate, the more intimate form of growth and that of the individual corallites is different. Of the four species described by Dybowski, only one (*T. tubulus*) is said to be fasciculate, and there are fistulæ also, but the septa in the two species differ widely.

Micro. Structure.—There is a thin proper wall, or theca, of dense structure presented either as a light or dark ring, usually the latter, followed by a moderate thickening of wavy, concentric stereoplasma; the structure of the fistulæ is precisely similar. The concentric laminæ of the thickened septal spines assume a cone-in-cone appearance. Thin sections also reveal another very interesting point in connection with these spines, viz., every here and there one or more sharp lateral denticles are seen to extend from the spines. These are very irregularly developed, as the transverse sections of some corallites exhibit none, whilst in others several spines are so provided. Another equally interesting point is that the mouths, or entrances into the fistulæ, are septal-spinose, and in one instance spines may be seen (Pl. XXVI, fig. 7) entering the tube itself. On the other hand, the tabulæ do not bear longitudinal spines as in *T. columnaris*, &c. It is not often possible, in one and the same section, to illustrate both the lamellar and spinose portions of a septum; in one section (Pl. XXVI, fig. 6), however, such is the case. On one side the corallite will be seen the more or less perfect organs, and on the other a series of rounded prominences which, I believe, represent the lamellar portions only.

Localities.—Old Limekilns Ridge, Humewood, near Yass, County Murray (*R. Etheridge*—Mining and Geological Museum): Hatton's Corner, Yass River, near Yass (shales below limestone), County Murray (*T. W. E. David, W. S. Dun*—Mining and Geological Museum; *R. Etheridge, A. J. Shearsby, S. R. Mort*—Australian Museum): Portion 103, Parish Warroo, east bank of Yass River (shales below limestone), County Murray (*C. Cullen*—Mining and Geological Museum; *R. Etheridge*—Australian Museum): Derrengullen Creek, a branch of the Yass River, Parish Yass, County King (*C. A. Süssmilch*—Technical College, Sydney): Mudgee Road, five miles from Wellington (*C. Cullen*—Mining and Geological Museum): Two miles east of Pine Creek, Euchareena, Parish Trudgett, Wellington District, County Wellington (*J. Hook*—Mining and Geological Museum).

Tryplasma Lonsdalei, *var.* scalariformis, *var. nov.*

(Plate XII, Figs. 2 and 3; Pl. XIV, Fig. 4; Pl. XXIV, Figs. 7, 8, and 8A; Pl. XXV, Figs. 1–4; Pl. XXVI, Figs. 8–10.)

Observations.—In company with typical examples of *T. Lonsdalei*, we meet with other colonies possessing the same general structure as the latter, but which may be distinguished as follows:—

1. Although many of the corallites have the same average diameter as the species in chief, there is always a certain number of others surpassing the maximum measurement of the latter, and varying from eight to ten millimetres, and even attaining fifteen, just previous to a bud bifurcation. This imparts to the corallum in general a much more robust appearance, which is quite appreciable to the naked eye alone.
2. The tabulæ are, however, the important factor in distinguishing this variety. In the first place, so far as my sections show, there are no clusters of closely-packed floors; but the latter are, as a rule, far apart and equidistant, and, in their regularity, remind one of the rungs of a ladder, hence the varietal name.
3. There is also a slight difference in the gemmation, in that the young corallites are united laterally for some distance before springing from one another; two to four buds.

Fistulæ were present (Pl. XXV, figs. 1, 2, and 3).

In the regularity of its tabulæ, this variety is akin to *T.* (*Acanthodes*) *tubulus*, Dybowski, *T.* (*Amplexus*) *tortuosa* (Phill.), Kayser, and *T.* (*A.*) *borussicus*, Weissermel.

Localities.—Portions 29, 39, and 63A, Molong District, Parish Narragal, County Gordon (*C. Cullen*—Mining and Geological Museum): Portions 60 and 65, Parish Boree Nyrang, County Ashburnham (*C. Cullen*—Mining and Geological Museum): Mudgee Road, five and a quarter miles from Wellington (*C. Cullen*—Mining and Geological Museum): Portion 210, Parish Nemingha, County Parry (*C. Cullen*—Mining and Geological Museum): Anticline at Boambolo Crossing, Murrumbidgee River (*A. J. Shearsby*—Australian Museum): Mouth of Euralie Creek, Yass River, County Murray (*R. Etheridge, A. J. Shearsby*—Australian Museum): Horse-shoe Bend, Murrumbidgee River (*C. Jenkins*—Geological Department, University): Limestone Creek, Silverdale, near Bowning, County King (*J. Mitchell*—Mining and Geological Museum): McEwan's Creek, Jenolan Caves, and track near Guide's House, Mount Victoria Road, Jenolan, County Westmoreland, (*R. Etheridge*—Australian Museum).

TRYPLASMA LONSDALEI, *var.* minor, *var. nov.*

(Plate XVI, Figs. 3 and 4; Pl. XXIV, Fig. 9; Pl. XXV, Figs. 6 and 7; Pl. XXVI, Fig. 11.)

Observations.—The principal varietal character of this coral is in a diametrically opposite direction to that of the var. *scalariformis*—the corallites are smaller than those of *T. Lonsdalei* proper.

The corallum is formed of fasciculate masses of considerable size, closely imitating in its growth that of fasciculate species of *Lithostrotion* and *Diphyphyllum*. The corallites do not exceed five millimetres in diameter, and vary between that measurement and four millimetres. The septal laminæ agree in number with those of the species in chief, but the spines are proportionately longer. There appears to be a complete absence of groups of close tabulæ, although the floors coincide in their distance apart with those of *T. Lonsdalei* proper. In general terms, its structure may be said to be that of the latter, but the corallites are of a decidedly smaller habit, and in consequence the colonies at once attract the eye of the collector in the field.

This variety is also more truly fasciculate than the species in chief, and the corallites are clustered much closer together; in fact, in a large number of instances, they are actually united laterally. The fistulæ are also well developed, and form a prominent feature in weathered specimens (Plate XXVI, fig. 11).

I have not seen any trace of budding; at the same time, it must be fairly common to form the large masses constituting this coral.

Locality.—Banks of Yass River, Portions 53, 126, and 161 (shale below limestone), Parish Yass, County King (*R. Etheridge*—Australian Museum): Hatton's Corner, Yass River, near Yass (shales below limestone), County Murray (*C. A. Süssmilch*—Technical College, Sydney).

Tryplasma delicatula, *sp. nov.*

(Plate XXII, Fig. 9; Pl. XXIII, Figs. 6 and 7.)

Specific Characters.—Corallum loosely fasciculate, of unknown dimensions, but probably large. Corallites long, cylindrical, straight or slightly flexuous, from one and a half to three millimetres in diameter, united laterally by their walls, or by fistulæ. Fistulæ short, of less diameter than the corallites, horizontal, and placed at different levels. Septal lamellæ of two orders, primary and secondary, about thirty in a cycle; septal spines tooth-like, without lateral denticles, the secondary spines very short. Tabulæ complete and incomplete, the former at irregular distances apart, horizontal, concave, oblique or rolling, sometimes with a central depression, and at times provided with longitudinal spines; incomplete are vesicular, the vesicles triangular (in section), and marginal. Gemmation unknown.

Observations.—I do not feel justified in uniting this with *T. Lonsdalei*, although clearly of the same type, particularly of the var. *minor*. We have here a form not only with corallites of considerably less diameter and a much smaller habit, but also uniformly possessing thirty septal lamellæ, as against a considerable augmentation in *T. Lonsdalei* and its varieties. I was, further, always able to at once distinguish this species in the field, when *in situ* and in close contiguity to the former.

T. delicatula possesses the least number of septal lamellæ, in common with *T. vermiformis*, of any of our *Tryplasmæ*. I am not acquainted with anything like a perfect corallum, but judging from appearances, and its general resemblance to *T. Lonsdalei*, it must have grown to some size. The fistulæ are well developed for so fragile a form, and the septal spines are non-denticulate, but, as in *T. columnaris*, the tabulæ bear longitudinal spines.

Fistulæ have not been observed in *T. vermiformis*, nor vesicular tabulæ or tabular spines, the cut edges and ends of which are seen in thin transverse sections of *T. delicatula*, and notwithstanding the similarity in the same number of septal lamellæ, I believe the two corals to be distinct.

Locality.—Bank of Yass River, Portion 126 (shale below limestone), Parish Yass, County King (*R. Etheridge*—Australian Museum): Derrengullen Creek, a branch of the Yass River, Parish Yass, County King (*C. A. Süssmilch*—Technical College, Sydney.

Tryplasma vermiformis, *sp. nov.*

(Plate XI, Fig. 1; Pl. XXIII, Figs. 4 and 5.)

Specific Characters.—Corallum probably fasciculate and large. Corallites long, erect, cylindrical, straight, united laterally by their walls, or simply contiguous and separated by variable interspaces; section round, and diameter five millimetres. Epitheca apparently quite smooth. Bourrelets represented by a series of delicate, regular, equal rings of very low convexity, and following one another closely. Septal lamellæ twenty-eight to thirty, primary and secondary, and the separation distinctly marked; spines very delicate and acute, the secondary remarkably short. Tabulæ complete, distant, and regular, horizontal, very rarely slightly oblique. Gemmation compound-calicular-rejuvenescent, in two or four buds, the young corallites curving outwards from the parent.

Observations.—This remarkably simple form appears to be quite distinct from *T. Lonsdalei*, and worthy of a name. It is distinguished by—(1) the limited number of septa; (2) regularity and simplicity of the tabulæ; (3) apparent absence of radiciform processes and fistulæ.

The long, simple corallites seem to be quite smooth externally, the regular, equal, smooth bourrelets of low convexity giving to the tubes much the appearance of a worm, or caterpillar. I think the corallum must be described as fasciculate, for, although the specimens before me are, in a great measure, composed of fragments lying in all directions, still sufficient corallites remain in parallel and sub-parallel positions to indicate that the form of the corallum was that of large bundles as described, at least nine inches high by seven inches broad.

The septal lamellæ are less in number than in any other species, except one; and are remarkable for their well-defined separation into primary and secondary, as indicated by the length of the spines.

The tabulæ are very regular, almost always horizontal, spaced widely apart, and resemble the rungs of a ladder. In a transverse section the surface is always quite plain, without any trace of cut edges indicating the presence of irregular or vesicular tabulæ.

The method of budding in this species, of all our *Tryplasmæ*, more closely resembles that of *Pycnostylus*, Whiteaves, two or four buds. In Pl. XXIII, fig. 5, is a very beautiful example of the latter condition. Whiteaves remarks on the budding of *P. guelphensis* :—" Natural transverse sections of this species . . . . show a quadripartite, and more rarely a tripartite, division of the corallites. The appearance might be supposed to be the result of fission, rather than of calicular gemmation, but is really due to the coalescence of the inner walls of the corallites immediately after budding." Each bud in *T. vermiformis* is deltoid in transverse section, the four buds occupying the whole of the calice, the apices of the deltoids leaving a small free space between them in the centre (Pl. XXIII, fig. 5); each bud has already developed septa along its outer convex wall.

In many corallites the proper wall is very distinctly preserved as a thin dark circumferential line, with a narrow inner ring of stereoplasma. The same remark also applies to both the septa and tabulæ.

Locality.—Portion 9, Parish Boree Nyrang, County Ashburnham (*C. Cullen*—Mining and Geological Museum).

TRYPLASMA CONGREGATIONIS, *sp. nov.*

(Plate XIII, Fig. 1; Pl. XXI, Fig. 10; Pl. XXIII, Fig. 10.)

Specific Characters.—Corallum of sub-fasciculate masses of corallites connected by very numerous fistulæ. Corallites long, erect, cylindrical, sub-parallel, contiguous to one another or separated by various intervening distances, enlarging and contracting in their course; in section more often oval than round, with their longest diameter from ten to fifteen millimetres. Epitheca thin, and ornamented with delicate, equidistant, raised, encircling threads, here and there interspersed with thicker ones. Fistulæ very numerous, round or oval, usually more or less equally spaced apart, at distances of about ten millimetres, tier above tier, and on the same level in contiguous corallites. Septal laminæ about thirty-five, primary and secondary; spines delicate, non-denticulate, and remarkably short. Tabulæ complete and incomplete, but more often the former; complete—horizontal, oblique, or rolling; incomplete—as lenticular vesicles, broader at one end than the other. Gemmation in paired buds (?).

Observations.—The sub-fasciculate colonies are of no inconsiderable size, but the exact dimensions are unknown. The long cylindrical corallites

are generally closely packed, although at times separated from one another by intervals of some extent. They are either erect or a little curved, and, when clustered, are freely united to one another by numerous fistulæ, which seem to be developed at regular intervals, tier above tier (Pl. XIII, fig. 1), and practically on the same level throughout the corallum.

The points chiefly relied on for specific separation are:—(1) Small number of the septal laminæ, and brevity and delicacy of the spines; (2) plentitude and regularity of the fistulæ.

When compared with some other species of this genus, the tabulæ present a far more regular appearance than most, with the exception of those of *T. columnaris* and *T. dendroidea*, which resemble them. This is one of the species in which the tabulæ, when viewed from above, exhibit the peripheral nicks, the impressions of the septal spines.

The gemmation is not fully known; two buds were certainly developed at one and the same time, but whether or no these were all, I am unable to say.

Microscopic sections reveal the presence of a very thin theca, visible only in well-preserved specimens, with a narrow stereoplasmic lining, which completely invests the laminæ, and coats the primordial spines. Here and there the latter thickening has the usual delicate cone-in-cone structure; but, in other instances, it is like the stereoplasmic wall lining, grey in colour, and structureless.

Localities.—Derrengullen Creek, a branch of the Yass River, and Barber's Creek, a branch of Derrengullen Creek, near Bowning, County King (*A. J. Shearsby*—Australian Museum; *C. A. Süssmilch*—Technical College, Sydney).

Tryplasma columnaris, *sp. nov.*

(Plate XV, Figs. 6; Pl. XIX, Fig. 5; Pl. XXIV, Figs. 2–5.)

Specific Characters.—Corallum in the form of solitary corallites, so far as known. Corallites long, columnar-cylindrical, straight or sometimes slightly curved, attaining a diameter of twenty-five millimetres; base obtusely pointed. Epitheca ornamented with fine, concentric, close, wavy lines. Rugæ in the form of obtuse rounded ridges. Bourrelets as fine concentric rings, the edges crenulated by the rugæ, irregularly spaced apart, but often close, sometimes developing into obtuse swellings rendering the

surface of a corallite uneven. Septal lamellæ strongly developed, sixty to eighty in number, primary and secondary; spines non-denticulate, the primary long and acicular, extending well on to the surfaces of the tabulæ, secondary spines short and thorn-like. Tabulæ numerous, close, complete, but more commonly incomplete, the former rolling, the latter forming lenticular vesicles; spines freely developed on the upper surfaces of the tabulæ. Gemmation unknown.

Observations.—*T. columnaris* is remarkable as being one of the three corals possessing spines on the tabulæ, a feature which at once separates it from the other species having a similar external appearance. In horizontal sections the spines are visible, either as dark spots scattered over the surface or as dark rings with a refractive centre.

Detached pieces of this coral, on external characters only, may easily be mistaken for large examples of *T. dendroidea*, but its highly lenticular vesicular tabulæ and spines will at once separate them.

The microscopic structure is interesting. The theca is, as usual, indicated by a thin dark circle, and within this is a stereoplasmic layer of variable width, although usually wide, and enveloping the septal spines unequally in different specimens. Some it encases in a uniform manner, rendering them obtuse; in others the stereoplasma accommodates itself to the outline of the spines, following their acicular form. This stereoplasma may be either homogeneous and structureless, or with the usual wavy cone-in-cone appearance. The spines on the tabulæ are similarly invested.

Localities.—Portion 4, Parish Boree Nyrang, County Ashburnham (*C. Cullen*—Mining and Geological Museum): Boree Creek, Portion 2, Parish Cudal, County Ashburnham (*C. Cullen—Ibid.*): Quedong, County Wellesley (*C. Cullen—Ibid.*).

Tryplasma, *sp.*

(Plate XIII, Fig. 2.)

Observations.—I am unable to refer these long corallites to either *T. congregationis*, *T. columnaris*, or *T. dendroidea*. From external appearance only it might easily be placed with the second, but my sections, which are not all that could be desired, do not show the presence of spines on the tabulæ, and there is no trace of gemmation; also, its close entombment in the matrix renders a detailed examination very difficult. The specimen consists of two

long, pipe-like corallites, one ten inches in length, retaining much the same diameter throughout. If the spines on the tabulæ are not to be regarded as a specific point in *T. columnaris*, these corallites might then be included in that species from the want of evidence to the contrary.

Locality.—Portion 77, Parish Eurimbula, County Gordon (*C. Cullen*—Mining and Geological Museum).

Tryplasma dendroidea, *sp. nov.*

(Plate XIV, Fig. I; Pl. XV, Fig. 5; Pl. XVIII, Figs. 2–6; Pl. XIX, Fig. 6; Pl. XXII, Figs. 11–15; Pl. XXIII, Fig. 9; Pl. XXIV, Fig. 6; Pl. XXVII, Figs. 3 and 4.)

Specific Characters.—Corallum consisting in the first instance of single corallites, which, by repeated quadripartite gemmation, give rise to a modified form of dendroid growth. Corallites long, cylindrical, erect, or slightly curved, with an average diameter of twelve millimetres, increasing to fifteen or even twenty immediately previous to budding. Epitheca ornamented with fine concentric line-ridges, close, with here and there a coarser one. Fistulæ seldom developed. Septal lamellæ fine, about fifty-five, primary only; spines thorn-like, short, very fine. Tabulæ complete, at variable distances apart, horizontal or convex, forming plane, solid floors on natural fracture; vesicular tabulæ very exceptional. Gemmation very marked and persistent, four rejuvenescent buds in opposite pairs, rapidly diverging from one another.

Observations.—The corallum of *T. dendroidea* assumes a more definitely dendroid form of growth than that of any other of our Australian species. It appears to consist of one (Pl. XVIII, figs. 2–4) or more long corallites in juxtaposition but separate, seldom ever united by fistulæ, increasing at intervals by the usual calicinal rejuvenescent budding in bunches of four, giving rise to a series of young corallites free laterally, conveying to the whole a peculiar and modified form of dendroid growth, but how frequently this takes place in a corallum I have no evidence to show.

The complete or greatest length attained by any one corallite is unknown, but in one instance (Pl. XVIII, fig. 3) the incomplete parent stem is seventy-five millimetres in length. It is, however, quite clear that the distance between points of gemmation varied considerably, for the offspring is but thirty millimetres long before it commences to again reproduce.

In consequence of the usually complete nature of the tabulæ, fracture across the stems easily takes place, and it is not uncommon to collect the coral

as a number of comparatively small discs, the latter representing one or more of the old visceral chambers. Another important feature is the plane even surface of the tabulæ on fracture, arising from the shortness of the septal spines. This character *T. dendroidea* bears in common with *T. congregationis*; indeed it is, in many ways, closely allied to the latter, and, had it not been for the marked development of the fistulæ, lesser number of septal lamellæ in a cycle, and presence of vesicular tabulæ in the latter, I would have felt inclined to unite the two forms.

I am not acquainted with the mode of reproduction in *T. columnaris*, but, over and above this, the present species is separated from that coral by the regularity of its tabulæ, the absence of accretion ridges to any degree of importance, and generally less robust appearance.

The principal characters of *T. dendroidea* are:—(1) Mode of growth; (2) preponderance of complete tabulæ; (3) extent of surface of the latter on fracture.

T. (*Amplexus*) *stigmatophorus*, Sandb.fr.,[1] from the Devonian of Nassau, is probably allied here, having the same large complete tabulæ, with peripheral septal spine impressions.

Localities.—Derrengullen Creek, a branch of the Yass River, Portion 10, Parish Yass, County King (*C. Cullen and W. S. Dun*—Mining and Geological Museum; *A. J. Shearsby*—Australian Museum): Barber's Creek, a branch of Derren-gullen Creek, Parish Yass, County King (*A. J. Shearsby*—Australian Museum.

Tryplasma derrengullenensis, *sp. nov.*

(Plate XXII, Figs. 5–8.)

Specific Characters.—Corallum simple. Corallites solitary, small, turbinate, ob-conical, or elongate and twisted, irregularly undulated in consequence of the unequal development of bourrelets. Radiciform processes well developed, always on one side a corallite more than the other, clustered. Epitheca complete, ornamented by scalloped encircling lines. Rugæ broad. Bourrelets prominent for so small a species, representing the margins of pre-existing corallites. Calice deep, nearly straight-walled; floor flat. Septal lamellæ very numerous and short, primary and secondary, the former leaving deep furrows in casts, the latter shallow; spines thorn-like, the primary much larger than the secondary, one to two cycles in old visceral chambers, and

[1] Sandberger, fr.—Verstein. Rhein. Schich. Nassau, Lief. 8, 1854, t. 36, f. 14*b*.

very numerous and close set one above the other in the calice. Tabulæ complete, at irregular distances apart, but on the whole close set, horizontal or slightly oblique, bearing longitudinal scattered spines. Gemmation compound, four calicular-rejuvenescent buds; budding may commence at a very early stage.

Observations.—A very interesting little species, the smallest of our *Tryplasmæ*. The remarkable depth of the calice (Pl. XXII, fig. 6) is only equalled by the number of septal spine cycles. There appear to be more secondary than primary cycles, twelve cycles of the former and ten of the latter. The complete tabulæ are so closely set that not more than one or two cycles could have existed in each old visceral chamber or intertabular space. The upper surfaces of the tabulæ are minutely spined, and the spines irregularly scattered; this is the third Australian species possessing these interesting structures.

Radiciform processes are confined to one side of a corallite, leading to the belief that in the living state the coral was inclined from the vertical.

The bourrelets are a prominent feature in *T. derrengullenensis*, giving an irregular, highly crinkled outline to the corallites. Their margins are delicately festooned by the fine epithecal lines passing over the rugæ, in a measure resembling the European *T. tubulatum*.

This, of all our Australian species, approaches nearest in outward form to the European *T.* (*Pholidophyllum*) *tubulatum*, Schl., and also to *T.* (*Acanthodes*) *rhizophorus*, Dyb., and *T.* (*A.*) *Eichwaldi*, Dyb. If Lindström is correct in referring *Cyathophyllum radicula*, Rominger, to his *Pholidophyllum*, it also may possibly prove to be nearly allied to *T. derrengullenensis*.

Locality.—Limestone Creek, near Bowning, Parish Derrengullen, County King (*A. J. Shearsby*—Australian Museum; *W. S. Dun*—Mining and Geological Museum).

Tryplasma wellingtonensis, *Eth. fil.*

(Plate XVI, Figs. 5–10; Pl. XXI, Figs. 11 and 12; Pl. XXII, Figs. 2–4.)

Tryplasma wellingtonensis, Eth. fil., Rec. Geol. Survey N. S. Wales, 1895, IV, Pt. 4, p. 160, t. 21–22.

Specific Characters.—Corallum in the early stages simple and solitary but by repeated calicinal gemmation in single buds forming strings of corallites. Corallites turbinate, or turbinate-conical when young, becoming more cylindrical in advanced growth, and sometimes twisted or bent upon

themselves; section circular; bases of parent corallites pointed, or expanded. Radiciform processes occasionally developed, long, stout. Bourrelets feebly developed, but represented chiefly by the projecting margins of old calices. Calice deep and straight-walled, non-expanding or bell-mouthed. Septal lamellæ about fifty in number, of two orders, primary and secondary, the former short; primary spines well developed, thorn-like, not laterally curved, and without lateral denticles; secondary spines as mere tubercles on the free edges of the secondary lamellæ. Tabulæ very numerous, complete or incomplete; the former delicate, close or widely separated, horizontal, oblique, or rolling; incomplete forming wedge-shaped, irregular, or lenticular vesicles. Gemmation single, calicinal or calicino-marginal, the former at once filling the parent calice, the latter springing from the edge of the parent calice by an attenuated base; in either case continuing in the same plane as the parent, or immediately diverging therefrom.

Observations.—This species is a characteristic coral of the Wellington Cave Limestone, and is interesting as presenting some very instructive examples of calicinal gemmation in single buds.

The corallites of *T. wellingtonensis* are always simple and solitary in the first instance, and do not give rise to sub-composite bunches even to the same degree as *T. princeps*, but by ordinary calicinal budding produce single lines of successively developed individuals, but to what extent this was carried on there is no evidence to show. As the corallites increased in growth, they took on a more cylindrical and less turbinate appearance, corallites here and there becoming twisted, or even bent on themselves. The base of the original, or first corallite, is either pointed obtusely or expanded, as if forming a base of attachment; there are no fistulæ. Bourrelets, or accretion rings, are represented by the edges of old calices where a younger corallite has grown rapidly within, possessing much the same diameter as the parent, and thus completely infilling it. At times a small peripheral space is left between the two, in which the tooth-like septal spines are just visible. The deep and straight-walled calice does not appear ever to expand as in *T. liliiformis*. The bottom is usually uneven, from the rolling nature of the tabula forming it.

No opportunity having arisen of examining an absolutely unoccupied or perfect calice, the precise number of septal lamellæ is still an open question; but judging from several computations, the total complement must have been fifty, more or less. There is a marked difference between the

difficult to distinguish the remains of the old cups from particularly strong and well-marked 'accretion ridges.' There is, however, strong reason for believing that the production of accretion ridges, and the simple form of calicular gemmation just alluded to, are merely different stages of the same physiological process." This explanation can be appreciated by a glance at (Pl. XVI, figs. 5 and 6.)

Sections prepared for the microscope reveal the presence of a thick and dark-coloured outer wall, inwardly invested by an ample stereoplasmic layer, which also follows the septal spines, and, in fact, at times represents them, without the presence of primordial laminæ.

On the question of dissepiments, I formerly wrote as follows[1] :—" In a coral with such remarkably short and distally free septa, dissepiments would not be expected, but at times a single dark plate is developed. . . . It is, in all probability, not formed by a series of dissepiments in a single line, but is the primitive theca in the substance of the outer investment, and septa traversing this zone have an intra- and extra thecal portion. In a rather more complete section . . . . an inner ring is visible which might be taken for a further series of dissepiments; it is, however, a second corallite springing from within the older one."

The principal characters relied on to distinguish this species are—(1) form of the corallites; (2) marked distinction between the two orders of the septal lamellæ; (3) simple calicinal gemmation; (4) non-expansion of the calice edge.

Locality.—Wellington Caves, near Wellington, County Wellington (*J. Sibbald*—Mining and Geological and Australian Museums).

Tryplasma, *sp.*

(Plate XVI, Figs. 1 and 2; Pl. XXII, Fig. 16; Pl. XXIII, Fig. 8.)

Observations.—The subject of the above figure appears to be allied to *T. wellingtonensis*, but still presents an important point of difference. The corallum evidently consisted of an aggregation of corallites produced by repeated budding, which was, I think, calicinal, notwithstanding the deceptive parietal appearance of the two corallites, one above the other, in the left central line; the three buds at the lower left-hand corner appear to be calicinal also. The septal apparatus consists of stout vertical laminæ,

[1] Etheridge—Rec. Geol. Survey N. S. Wales, 1895, IV, Pt. 4, p. 162.

and short, blunt spines, forty-five to fifty in number, and all of one order. Some of the corallites were also connected by large fistulæ; another very striking feature lies in the complete and, at times, widely separated tabulæ.

Some aspects of the growth of this coral recall the structure of *T. wellingtonensis*, but, on the other hand, the corallites of the latter are not, so far as known, aggregated into masses. The tendency of the calice to expand reminds us of the appearance of *T. liliiformis*. For the present, the identity of this coral must remain in abeyance.

Locality.—Geuric, near Wellington, County Lincoln (*W. Anderson* and *P. T. Hammond*—Mining and Geological Museum).

Tryplasma (?) Murrayi, *Eth. fil.*

(Plate XXVIII.)

***Tryplasma Murrayi*, Eth. fil., Geol. Survey Vict. Progress Report, No. XI, 1899, p. 32, t. A., f. 1-3.**

Specific Characters.—Corallum consisting of bundles or bunches of corallites, the precise ultimate growth unknown. Corallites of vigorous growth, long (up to four inches), cylindrical, straight, or a little curved, often partially united externally by their walls, and with a maximum diameter of half an inch. Wall much thickened by secondary deposit. Epitheca delicate, the lines very close and wavy. Fistulæ and radiciform processes not observed. Bourrelets irregularly developed, rendering the corallite surfaces uneven. Rugæ flat, separated by grooves indicating the peripheral ends of the septal lamellæ. Calices deep and straight-walled. Septal lamellæ very numerous, about fifty, narrow, apparently of one order only; septal spines very numerous, short, and stout. Special endothecal tissue present as one or two cycles of dissepimental cells. Tabulæ unknown. Gemmation apparently calicinal, in single buds.

Observations.—Through the courtesy of the Secretary for Mines and Water Supply, Melbourne, I have been able to restudy the type specimens of this species, supplemented by additional material. Prof. W. Baldwin Spencer, Director of the National Museum, has also sent me a fine example from Waratah Bay. The result of this re-examination is the foregoing amended description, but even this is imperfect from the fact that through the absence of sections prepared for the microscope I am unable to study several important points of structure.

It is, however, necessary to explain that I now know my original description of *T.* (?) ***Murrayi***, included two distinct corals. Although suspected for some time, I only became convinced of this on receiving the National Museum specimens. In each of the examples from the Geological Survey collection the larger corallites (*T.* (?) ***Murrayi*** restricted) are intermingled with a number of much smaller, more or less irregular tubes; these I took to arise from the larger corallites as the result of repeated parietal budding, more than one apparent junction being present. The specimen from the National Museum is free of this second coral, and after a long and tedious examination I find that the internal structure of these tubes is purely cystoid-vesicular. I, therefore, restrict the name *T.* (?) ***Murrayi*** to the larger cylindrical corallites.

Whilst possessing one of the most important and essential characters of *Tryplasma*, the large corallites depart from the structure or typical members of the genus by the presence of peripheral endothecal tissue in the form of from one to two cycles of calcareous plates passing from one septal lamella to the next one, and apparently (so far as my limited opportunity for examination has gone) enveloped, like the septal spines, with the exception of the actual apices, in a remarkably thick secondary investment. These transverse plates are faintly visible in the only section (imperfect) I have been able to prepare for the microscope (Pl. XXVIII, figs. 3 and 7), but on the weathered surface of a corallite (Pl. XXVIII, fig. 5) they are much more apparent, and are again seen in a semi-vertical natural section of a portion of a wall (Pl. XXVIII, fig. 6). The close resemblance of these plates to dissepimental tissue cannot be denied, although the tissue generally is scanty. It introduces an element of structure unlike that of any other member of the genus.

It is difficult to arrive at the precise mode of growth in *T.* (?) ***Murrayi***, but the corallites would appear to form more or less sub-compound bunches, the individual members here and there close enough together to become united to one another for some portions of their course by their walls. Some of the old calices present a double wall on fractured transverse surfaces, as if one corallite had sprung up within the other. It would appear from this that we have here true calicinal budding.

The septal apparatus of *T.* (?) ***Murrayi***, is strictly on the lines of *Tryplasma*, marginal longitudinal lamellæ distally produced into spines. The lamellæ were very numerous, the spines in the calices densly packed,

and in the only naturally fractured longitudinal section exposed, although the sides of the corallite in question are crushed together (Pl. XXVIII, fig. 4), the presence of the spines is shown throughout. I am unacquainted with the nature of the tabulæ.

The largest specimen is a cluster of corallites six and a half inches by three and a half inches, the longest individual corallite seen measuring four inches.

It is almost needless to remark that the structure of *T.* (?) ***Murrayi*** does not strictly conform to the generic characters embracing the whole of the typical species; it is, therefore, an altogether aberrant form of *Tryplasma*.

The species is named in honour of Mr. R. A. F. Murray, formerly Government Geologist of Victoria.

Locality.—Waratah Bay, near Wilson's Promontory, S.E. Victoria (*Geological Survey of Victoria and National Museum Collections, Melbourne*).

TRYPLASMA LILIIFORMIS, *sp. nov.*

(Plate XIV, Figs. 2 and 3; Pl. XV, Figs. 2–4; Pl. XVII, Figs. 7 and 8; Pl. XXIV, Fig. 1; Pl. XXV, Fig. 8; Pl. XXVII, Figs. 1 and 2.)

Specific Characters.—Corallum aggregate, hardly sub-compound, nor strictly fasciculate. Corallites liliaciform, stem-like below, with a diameter of five-eighths of an inch, expanding above into bell-shaped calices, two and a half to three inches in diameter; base sometimes pedunculate. Proper wall narrow. Epitheca delicate, thin. Rugæ flat. Radiciform processes long and well developed, irregularly scattered on the stems or basal portions of each corallite, and sometimes to be seen immediately below the calice margins. Calices wide and bell-mouthed, deep, with the bottoms flat or slightly concave. Septal lamellæ very numerous, mere ridges, about fifty-eight in the stems and eighty in the calices, primary and secondary; spines short and blunt, horizontal or slightly projecting upward. Tabulæ very numerous, complete and incomplete; complete tabulæ horizontal, concave, or rolling, close in the stem, but much wider apart near the calice; incomplete forming long, large, and often irregularly lenticular vesicles. Gemmation compound-calicular-rejuvenescent, two to three (? four) buds.

Observations.—The corallum of *T. liliiformis* is never compound in the strict sense of the word, nor can it be described as fasciculate, but the corallites appear to be aggregated into loosely constructed colonies. The corallites are remarkably persistent in form, resembling the calyx of a liliaceous plant on a stem. They are more or less erect, sub-parallel, and not twisted or tortuous. The radiciform processes are freely developed and often long (Pl. XIV, fig. 3; Pl. XXVII, fig. 1), for, irrespective of those attached to corallites, the surfaces of matrix hand-specimens are dotted with numerous portions and cross-sections of these rootlets; fistulæ proper appear to be absent.

The bell-mouthed calices are deep, in a few examples very deep, and in their lower portions straight-walled within. No other species of this genus appears to possess this form of calice so distinctly marked. Some of the bell-mouths attain to two and three quarter inch in diameter (Pl. XXVII, fig 1).

The greatest number of septal lamellæ counted in the calices is eighty, but in the stem-like portions the number is less. The difference in length of the primary and secondary spines is but slight; neither curved spines nor lateral denticles have been observed.

The tabulæ are very numerous, the complete floors regular as a rule, often wide apart, and not spined. When the plane of a cycle of septal spines is coincident with that of a tabula, peripheral nicks are left on natural transverse fracture. The vesicles formed by the incomplete tabulæ vary much in shape when seen in longitudinal section, but the elongate lenticular outline predominates.

In a transverse section prepared for the microscope, the proper wall when preserved appears as a thin dark circle, with an inner zone of wavy stereoplasma encasing the septal laminæ. In a longitudinal section the primordial line of the tabulæ is sometimes visible, and there is always a secondary thickening of greater or less extent; the stereoplasma of the wall and that of the tabulæ are one, and continuous without a break, but that of the wall investment is distinctly wavy and that of the tabulæ laminar.

T. liliiformis possesses some characters in common with *T. wellingtonensis*, but the following points will separate them:—(1) The Wellington species does not possess the same stem-like prolongation; (2) the calices are not bell-mouthed; (3) Gemmation is by single buds only; (4) the young corallites at once become turbinate, or some slight modification of this; (5) the distinction between the primary and secondary septal spines is very marked.

At first sight, the stem-like portion of the corallites, and the long corallites of *T. dendroidea* would appear to be one and the same. There is, however, this marked difference:—In the former the tabulæ are almost always crowded together, irregular, and, more often than not, vesicular, whilst the tabulæ of the latter are conspicuous by reason of their comparative regularity, horizontality, and rare vesicular nature. I freely confess I was for a long time in doubt how closely these forms were related to one another, for in *T. liliiformis* the bell-mouthed calices are supported with stem-like continuations of unknown length resembling the corallites of *T. dendroidea*.

The points relied on for specific separation are chiefly:—(1) Form of the corallites; (2) copious development of radiciform processes.

Of European species, *T.* (*Calophyllum*) *eurycalyx*, Weissermel, is very closely allied here, both in the form of the calyx and method of budding.

Localities.—Hatton's Corner, Yass River, near Yass, County Murray (Geological Department, University): Derrengullen Creek, a branch of the Yass River, Portion 10, Parish Yass, County King (*C. Cullen*, *W. S. Dun*, and *A. J. Shearsby*—Mining and Geological Museum; *A. J. Shearsby*—Australian Museum): Barber's Creek, a branch of Derrengullen Creek, Parish Yass, County King (*A. J. Shearsby*—Australian Museum): North-east corner of Portion 103, Yass River, Parish Warroo, County Murray (*R. Etheridge*—Australian Museum): Seven miles west of summit of the Canoblas Range, near Orange, County Ashburnham (*J. M. Curran*—Australian Museum): Parish Barton, County Ashburnham (*C. A. Süssmilch*—Technical College, Sydney).

Tryplasma princeps, *sp. nov.*

(Plate XV, Fig. 1; Pl. XVII, Figs. 1–6; Pl. XVIII, Figs. 1 and 7; Pl. XIX, Figs. 1–3; Pl. XX; Pl. XXI, Figs. 1–9; Pl. XXII, Figs. 1 and 10; Pl. XXIII, Figs. 1–3.)

Specific Characters.—Corallum consisting of simple solitary corallites, ultimately forming, by repeated budding, sub-compound masses or bunches. Corallites cylindrical to cylindro-ob-conical, large, stout, straight or rather curved, expanding slowly upwards from a more or less pointed base, attaining a length of at least eleven inches, by two and a half inches in transverse diameter; section circular or oval. Epitheca ornamented by close, encircling lines. Radiciform processes well developed, large, but irregularly distributed,

chiefly present on the basal half of each corallite, single or in groups. Fistulæ present in the rejuvenescent corallites only. Rugæ fine. Calice deep and large, nearly straight-walled within. Septal laminæ stout and strong, sixty-five to eighty, barely differentiated into primary and secondary; spines practically of one length, short, stout, occasionally laterally curved, but not denticulated. Tabulæ highly developed, at very irregular distances apart, sometimes much crowded together, complete and incomplete; complete tabulæ are horizontal or oblique, but more often rolling; incomplete tabulæ forming vesicles, either short and deep, and extending but a short distance from the wall, or elongately lenticular, and reaching nearly across the entire corallite; longitudinal spines absent. Gemmation compound-calicinal-rejuvenescent, copious, marginal or intra-marginal, and apparently only taking place in the gerontic calyx; buds at least thirteen, laterally united or connected by fistulæ.

Observations.—The corallites of *T. princeps* vary from cylindrical to cylindro-ob-conical, *i.e.*, a form varying between cylindrical and an elongate reversed cone (Pl. XVII, fig. 1; Pl. XX, fig. 1). The corallites are straight or gradually curved, and, in the latter condition, closely resemble in external appearance the large *Campophyllum giganteum*, Michelin, of the European Carboniferous Limestone. The upward expansion is slow, and proceeds from a more or less obtusely-pointed base. The large radiciform processes at the bases are a very prominent feature, represented by their wart-like broken bases, occurring singly or in groups. At Pl. XVII, fig. 1*c*, will be seen a long process flattened against the side of the corallite and below the bud. I am undecided whether to regard this as a part of a very long radiciform process, or as a fistula; if of the latter nature it is the only instance in the mature state of this species.

The septal laminæ are very numerous, and, so far as my sections reveal, do not appear to vary materially in number in different parts of the corallum. The septal spines are strongly developed, and sometimes laterally curved. The separation into primary and secondary is very arbitrary; in some instances (Pl. XVII, fig. 5) it is clear enough, in others it is quite lost, or it may appear in one portion of a corallite, and not in another; this separation seems to be influenced by the amount of stereoplasmic thickening present. As a rule, there is one cycle of spines in each old visceral chamber, or inter-tabular space; but, in rare instances, where the tabulæ are distant from one another, two, or even three cycles have been observed.

One marked feature in this coral is the irregularity of the tabulæ, both in their distance apart and in development.

Compound calicular budding is very prolific in *T. princeps*, and takes place either from the calice margin of the mature corallite, or is intra-marginal, the new corallites soon becoming detached from one another, except that fistulæ are sometimes seen to connect them. In the cylindrical specimen represented in Pl. XVII, fig. 1, there is one large bud; in portions of two other similar specimens, six are apparent. In a smaller ob-conical individual (Pl. XX, fig. 4), there are no less than thirteen young corallites, ten of them actually marginal, and the other three intra-marginal. In Pl. XVIII, fig. 1, are represented the two united portions of a really fine example of gemmation, the basal half consisting of three ob-conical corallites (Pl. XIX, fig. 1), of which the largest is seen to be giving off seven still younger individuals, five marginal and two intra-marginal. In the lower transverse view of the upper half (Pl. XIX, fig. 2), thirteen corallites are visible, including the seven already mentioned, the remaining six having budded above the level of the fractured half. The upper or growing surface of this group (Pl. XIX, fig. 3), displays twelve well-developed corallites, the thirteenth having been crowded out.

On the subject of compound calicular gemmation, so beautifully displayed in this corallum, Nicholson says:—"The primitive corallite throws up from its calicine surface two or more buds, which, after reaching a certain size, in most cases repeat the process. . . . . The necessary result of this is, that the aged corallum assumes the form of an inverted pyramidal mass, the base of which is formed by the primitive corallite. From the calice of this the secondary corallites diverge, and the surface of the entire mass is flattened or slightly convex. The calices of the secondary corallites, and the corallites themselves, may remain more or less completely separate. . . . . At other times the corallites are more intimately united by their walls, and the corallum becomes truly astræiform."[1] This paragraph admirably expresses the condition in *T. princeps*, except that not only are the younger corallites connected by their walls for a short length, but at times also by fistulæ.

It is difficult to imagine that the small buds represented in Pl. XX, fig. 4, could ever attain anything approaching even moderate dimensions as compared with the more highly vigorous parent. Nicholson has suggested

[1] Nicholson—Trans. R. Soc. Edinb., xxvii, p. 239.

an explanation of this, as follows :—"In this modification, the calice of the primitive corallite throws up a number of buds; but the former does not seem to feel the stimulus to gemmation till it has reached a great age, and a corresponding size. The result of this is, that the secondary corallites remain more or less aborted, and do not appear to have sufficient energy to repeat the process of budding. Hence, in these cases, we have the fully developed, and often comparatively gigantic parent corallite, surmounted by a tuft of small undeveloped secondary corallites, springing from different points on its calicine surface." [1]

In a horizontal section prepared for the microscope, the external wall appears as the usual dark circumferential line, sometimes with an inner zone of secondary stereoplasma, and sometimes without; the latter, when present, is bounded inwardly by a thin dark ring, which possibly represents the primitive theca. If this be so, there is then an intra- and extra-thecal portion; the wall stereoplasma is grey in colour, homogeneous, and dense. The supposed primitive theca is, more often than not, absent when the septal lamellæ abut against the external wall. These lamellæ may, or may not, consist of primordial septa, represented by dark rods, surrounded by stereoplasma, having a feathery cone-in-cone structure, and projecting a short distance into the visceral chambers; each cone-in-cone mass is separated from its neighbour by a thin fluctuating line. In the absence of the primordial septa, the surrounding stereoplasma and the fluctuating boundary lines are present all the same. The spines also differ in the same section; they may be short, blunt, and triangular, forming a serrated edge to the stereoplasmic ring, or a series of definite short spines.

In a longitudinal section the eye is at first attracted by the thickness of the wall stereoplasma, intersected by an occasional primordial septum. It will be observed that some of the free ends of the spines are upwardly turned, or hooked. The primordial tabulæ and their stereoplasmic thickenings are also plainly visible.

Pl. XXI, fig. 3, represents a section cut longitudinally and somewhat obliquely through the septal lamellæ immediately before becoming spinous; the primordial septa are distinctly visible. At first sight, these would appear to be dissepiments; but I regard these transverse lines as the cut ends of tabulæ only.

[1] Nicholson—Trans. R. Soc. Edinb., xxvii, p. 240.

The structure of the radiciform processes is concentric (Pl. XXII, fig. 10).

I have included under *T. princeps* what might, at first sight, appear to be two distinct corals, looking at the outward form only. As far as my examination has gone, all, however, possess a similar internal structure. We see, in the first instance, the long cylindrical *Campophyllum*-like corallum (Pl. XVII, fig. 1), abruptly ending below in a much contracted and insignificant base, and bearing one bud above on the calcine margin. The next step in advance are the two corals (Pl. XX, figs. 3 and 5), each giving off six buds, the naturally-weathered longitudinal section (Pl. XX, fig. 2), and the spine-pitted specimen (Pl. XV, fig. 1). We may now turn to the subjects of Pls. XVIII, fig. 1; XX, figs. 1 and 4. At first sight these more elegantly shaped and rather ob-conical forms convey the impression of a distinct species, but, as already stated, the inner structure is the same as the cylindrical specimens, the gemmation is identical, and, if the central portion of Pl. XX, fig. 1, be taken only, there would be no distinguishing it from Pl. XX, fig. 5, or the central part of Pl. XVII, fig. 1. Lastly, we have before us the beautiful specimen, Pl. XVIII, fig. 1. If Pl. XX, fig. 1, be admitted to be conspecific with Pl. XVII, fig. 1, there is nothing to prevent Pl. XX, figs. 4 and 6, being so also.

I am in doubt as to the identity of Pl. XXII, fig. 1. The internal structure is that of this species, but the three very prominent bourrelet calice margins would imply that the original calicine disc gave off but a single bud at a time, each bud repeating the process in a similar manner to some individuals of *T. wellingtonensis*.

Lindström's illustration of his *Amplexus appendiculatus* of the Upper Silurian rocks of China would imply a close relationship with the present species.

Localities.—Boree Creek, Portions 2, 3, $12\frac{44}{1}$, Parish Cudal, County Ashburnham: Mandagery Creek, Portion 102, Parish Bell, County Ashburnham: Portions 84 and 92, Parish Culrindi, County Darling: Boundary, Portion 77, Parish Eurimbula, County Gordon: Portion 29, Parish Narragal, Molong District, County Gordon: east side of Portion 5, Parish Mumbil, County Wellington: Portion 98, Parish Gamboola, County Wellington: Portion 81, Parish Larras Lake, County Wellington: Jier's Farm, Ponto Road, eight miles from Wellington, County Lincoln: Portion 157, Parish Burdekin, County Inglis (*C. Cullen*—Mining and Geological Museum).

TRYPLASMÆ, *sps.*

Observations.—Specifically indeterminable corals have been met with at the following localities :—

1. Boree Creek, Portion $12\frac{11}{1}$, Parish Cudal, County Ashburnham (*C. Cullen*).
2. Boree Creek, Portion 3, Parish Cudal, County Ashburnham (*C. Cullen*).
3. Portion 39, Parish Narragal, County Gordon (*C. Cullen*).
4. Portion 13, Parish Eurimbula, County Gordon (*C. Cullen*).
5. Catambal Range, south of Wellington, County Gordon.
6. East side of Portion 5, Parish Mumbil, County Wellington (*C. Cullen*).
7. Portion 53, Parish Crawney, County Brisbane (*C. Cullen*).
8. Portion 51, Parish Turon, County Roxburgh (*M. Morrison*).
9. Mt. Gray Mine, Mt. Gray, eight miles south-south-east of Trunkey, County Georgiana (*T. A. Smith*).

PLATES AND EXPLANATIONS.

Plates X–XX were prepared and reproduced by Mr. A. E. Dyer, and Plates XXI–XXVIII were drawn by Mr. F. R. Leggatt, and lithographed by Mr. E. W. Minchen, at the Government Printing Office, Sydney, under the direction of Mr. W. A. Gullick, Government Printer.

PLATE XX.

Tryplasma princeps, *Eth. fil.*

Fig. 1. Cylindro-obconical corallite, with radiciform basal processes (*a*).

Fig. 2. Natural longitudinal section of a similar specimen, with crowded tabulæ.

Fig. 3. Calice of a cylindrical example, with six rejuvenescent buds.

Fig. 4. A much decorticated, slightly curved coral, with thirteen calicino-marginal rejuvenescent buds.

Fig. 5. Calice similar to Fig. 3, with six rejuvenescent buds.

Fig. 6. Another example, in which there are five small calicino-marginal buds.

PLATE XXI.

Tryplasma princeps, *Eth. fil.*

Fig. 1. Decorticated obconical corallite, with pitted grooves representing the septal lamellæ and spines, the longitudinal ridges indicating the rugæ.

Fig. 2. A portion of the surface towards the base of the same corallite (Fig. 1) more highly magnified.

Fig. 3. A portion of a longitudinal section of a corallite, prepared for the microscope, showing the bases of the septal lamellæ, and the tabulæ.

Fig. 4. The lower left-hand corner of Fig. 3 highly magnified, displaying the primordial septal lamellæ.

Fig. 5. Transverse section of a corallite, prepared for the microscope, with the thick peripheral septal zone, septal spines, and cut edges of tabulæ.

Fig. 6. A small portion of the septal zone, highly magnified.

Fig. 7. Longitudinal section, prepared for the microscope, showing calice, septal spines, and tabulæ.

Fig. 8. Transverse section of a smaller corallite, prepared for the microscope, exhibiting the septal spines and cut edges of tabulæ.

Fig. 9. A few of the septal spines, highly magnified.

Tryplasma congregationis, *Eth fil.*

Fig. 10. Portions of three corallites in longitudinal section, prepared for the microscope, exhibiting, regular complete tabulæ; one of the corallites sends forth two fistulæ, and two others are seen in transverse section in the matrix.

Tryplasma wellingtonensis, *Eth fil.*

Fig. 11. Transverse section of portion of a corallite, prepared for the microscope, showing the septal spines and vesicular tabulæ.

Fig. 12. A portion of Fig. 11 highly magnified.

PLATE XXII.

Tryplasma princeps, *Eth fil.* (?)

Fig. 1. A large corallite, with strong bourrelets or accretion rings, in which it departs widely from this species.

Tryplasma wellingtonensis, *Eth. fil.*

Fig. 2. A turbinate corallite, with a portion of the wall removed, showing the septal lamellæ grooves and holes left by the septal spines.

Fig. 3. A small calice, displaying the primary septal spines and secondary granules, tabulæ, and radiciform processes.

Fig. 4. Some of the septal spines and granules from Fig. 3 enlarged.

Tryplasma derrengullenensis, *Eth. fil.*

Fig. 5. A small turbinate corallite, with bases of radiciform processes.

Fig. 6. A more obconical corallite, showing the remains of the calice with the grooves left by the primary and secondary septal lamellæ, and the holes by the septal spines of the two orders.

Fig. 7. A number of the septal grooves and spine holes highly magnified.

Fig. 8. A more or less distorted corallum, turbinate below, cylindrical above, with bases of radiciform processes.

Tryplasma delicatula, *Eth fil.*

Fig. 9. Transverse section of two corallites prepared for the microscope.—x 3.

Tryplasma princeps, *Eth. fil.*

Fig. 10. Transverse section of a radiciform process prepared for the microscope.—x 3.

Tryplasma dendroidea, *Eth. fil.*

Fig. 11. Parent corallite and four buds.

Fig. 12. „ and three buds.

Fig. 13. Polished longitudinal section of part of a corallite, showing regular complete tabulæ.

Fig. 14. Transverse section of a corallite, prepared for the microscope, with sharp acicular septa spines, and wide central tabulate area.—x 2.

Fig. 15. Transverse view of a naturally-fractured corallite, displaying a tabulum with circumferential septal nicks.

Tryplasma, sp.

Fig. 16. Transverse section prepared for the microscope of a corallite of the coral represented in Pl. XVI, Figs. 1 and 2, showing the thickened wall and septal teeth.—x 2.

PLATE XXIII.

Tryplasma princeps, *Eth. fil.*

Fig. 1. A longitudinal section, prepared for the microscope, of a large cylindrical corallite, showing the thickened wall and broken-up tabulæ.

Fig. 2. A similar section of part of another cylindrical corallite, exhibiting the thickened wall, and septal spines; the tabulæ are less broken up, some complete, others forming lenticular vesicles.

Fig. 3. A portion of the wall of Fig. 2, showing the septal spines.

Tryplasma vermiformis, *Eth fil.*

Fig. 4. Longitudinal section of a corallite, prepared for the microscope, showing the distant, complete, and horizontal tabulæ; in one of the latter is a peculiar medium dip.—x 2½.

Fig. 5. Transverse sections of four corallites, prepared for the microscope; one of these shows a very beautiful example of compound calicular rejuvenescent budding.

Tryplasma delicatula, *Eth. fil.*

Fig. 6. Longitudinal section of several corallites, with fistulæ and tabular spines.—x 2.

Fig. 7. A small portion of one of the corallites highly enlarged.

Tryplasma, sp.

Fig. 8. Longitudinal section, prepared for the microscope, of portions of two corallites of the coral represented in Pl. XVI, Figs. 1 and 2, showing the septal spines and complete tabulæ.—x 2.

Tryplasma dendroidea, *Eth. fil.*

Fig. 9. Transverse section of a corallite, prepared for the microscope, showing delicate short-acicular septal spines, and the wide tabulate area.—x 2.

Tryplasma congregationis, *Eth. fil.*

Fig. 10. Transverse section of one and a half corallites, prepared for the microscope, with similar septal spines to those in Fig. 9. In the right-hand half-corallite is a portion of a rejuvenescent bud (?).

PLATE XXIV.

Tryplasma liliiformis, *Eth. fil.*

Fig. 1. Portion of a corallite in longitudinal section, prepared for the microscope, exhibiting a portion of the calice and tabulæ below. –x 2.

Tryplasma columnaris, *Eth. fil.*

Fig. 2. Longitudinal section of portion of a corallite, prepared for the microscope, displaying the thick solid walls, septal spines, complete and incomplete tabulæ and spines thereon.—x 2.

Fig. 3. Similar transverse section, exhibiting the cut edges of vesicular tabulæ, and the cut ends of the vertical spines.—x 2.

Fig. 4. A few of the cut ends (Fig. 3) of the tabular spines more highly magnified.

Fig. 5. Another transverse section of a corallite prepared for the microscope. Here the wall is very much thickened, and the primary septal spines greatly elongated; the vertical spines are again visible.—x 2.

Tryplasma dendroidea, *Eth. fil.*

Fig. 6. Longitudinal section of a small portion of a corallite, prepared for the microscope, exhibiting characteristic tabulæ.—x 2.

Tryplasma Lonsdalei, *var.* scalariformis, *Eth. fil.*

Fig. 7. Transverse sections of two corallites, prepared for the microscope; the upper shows a rare feature in this species—the cut edge of an incomplete tabulum.—x 2.

Fig. 8. Similar longitudinal section, exhibiting the regular step-like tabulæ.—x 2.

Fig. 8*a*. Transverse section of a corallite, displaying the parent corallite and three rejuvenescent buds.—x 2.

Tryplasma Lonsdalei, *var.* minor, *Eth. fil.*
